14 **Abstract**

15 In this study, we fabricated nano-capillary emitter arrays for stable ion emission of ionic liquid
16 electrospray thrusters, employing the fabrication of field emitter arrays or gated nano electron
17 sources. A nano-capillary emitter was successfully fabricated with a 100–300-nm capillary
18 diameter, which prevented ionic liquid leakage by significantly increasing the fluidic
19 impedance of the ionic liquid compared to a previously proposed emitter. An ion emission
20 experiment was conducted with 1-ethyl-3-methylimidazolium dicyanamide as the propellant.

21 Ion emission started at a low voltage of 61 V owing to a small gap of approximately 1 μm
22 between the emitter and extractor electrode. The maximum current density was 43 mA cm^{-2} on
23 the positive side and -13 mA cm^{-2} on the negative side without leakage of the ionic liquid,
24 which was more than 100 times higher than that of conventional electrospray thrusters.
25 Moreover, we obtained continuous ion emission without current intercepted by the extractor.
26

27

28 **1. Introduction**

29 As nanosatellites (1–10 kg) can be developed at low cost and in a short period of time, several
30 hundreds of them are launched per year.¹⁾ Recently, a wide variety of uses for satellites have
31 been proposed, including advanced missions, such as communication and earth observation by
32 a satellite constellation and deep space exploration. These missions require thrusters for active
33 orbit control to perform formation flight and orbit transition.^{2,3)} However, thrusters mounted on
34 nanosatellites are subject to strict size restrictions. Although ion thrusters have been mounted
35 on a 50-kg-class microsatellite and successfully operated in space,⁴⁾ it is difficult to mount them
36 on nanosatellites due to their massive and bulky gas supply system. The entire propulsion
37 system mounted on nanosatellites should fit within a cube approximately 10 cm on a side; thus,
38 the area of the thruster head is also restricted to approximately several centimeters in diameter.
39 Electro spray thrusters using ionic liquid as the propellant can be easily miniaturized because
40 they do not require a gas supply system; therefore, many studies have recently been conducted
41 on this topic.^{5–10)}

42 Figure 1 presents a schematic of the ion source of an ionic liquid electro spray thruster.
43 The ion source mainly consists of an emitter array and an extractor. The emitter array contains
44 multiple capillaries with sharp tips from which ions are emitted. When a voltage is applied
45 between the emitter and extractor, the electric field is concentrated at the emitter tip, which
46 deforms the ionic liquid. Ion emission starts as the force of the field overcomes the back

47 pressure caused by the surface tension of the liquid. The emitted ions are accelerated
48 downstream to produce thrust. The ionic liquid consists of only positive and negative ions
49 without solvent.¹¹⁾ Due to the Coulomb force between the ions, the vapor pressure of the ionic
50 liquid is negligible. Therefore, the ionic liquid can exist in the liquid phase even in vacuum,
51 simplifying the propellant feed system and reducing the size of the entire propulsion system.

52 However, the thrust produced by electrospray thrusters per emitter is too small, and
53 the thrust density ($\sim 10 \mu\text{N cm}^{-2}$) is less than one-tenth that of ion thrusters ($> 100 \mu\text{N cm}^{-2}$).¹²⁾
54 Increasing the emitter density is a possible method for improving the thrust density. In previous
55 work, we proposed a high-density emitter array employing the fabrication of field emitter arrays
56 (FEAs) or gated nano electron sources.^{13,14)} An emitter density of 4 million emitters cm^{-2} was
57 achieved, which was approximately 10,000 times higher than that of conventional electrospray
58 thrusters.⁵⁻¹⁰⁾ In a previous study, Spindt reported field-ionization sources for mass
59 spectrometry employing the FEA process, which ionized the analyte gas by applying a high
60 voltage of the order of 1 kV to the emitters.¹⁵⁾ In our previous work, the ion sources emitted
61 ions from an ionic liquid, not gas, and the driving voltage was less than 100 V.¹³⁾

62 In an ion emission experiment with the high-density emitter array fabricated in our
63 previous study, the maximum current density was -1.4 mA cm^{-2} and 0.85 mA cm^{-2} for the
64 negative and positive ion currents, respectively.¹³⁾ These values were approximately three times
65 higher than the current density achieved by conventional electrospray thrusters;⁵⁾ however, they
66 were still insufficient in consideration of the increase in emitter density. After investigation, we

67 detected leakage of the ionic liquid to the outside of the extractor, which inhibited stable ion
68 emission. To solve the leakage problem, it may be effective to increase the fluidic impedance
69 by an extremely narrow flow path of the ionic liquid.

70 In this paper, we fabricated an emitter array with a nano-sized emitter capillary that
71 can be 100–300 nm in diameter and greatly increases the fluidic impedance. After fabrication,
72 an ion emission experiment was conducted to evaluate the effect of the narrower flow path of
73 the ionic liquid. The purpose of this study is to present a fabrication method for nano-capillary
74 emitter arrays employing the fabrication of FEAs and to demonstrate stable ion emission by the
75 nano-sized emitter capillary. In Sect. 2, we present the design of the nano-capillary emitter array
76 and describe its fabrication procedure. In Sect. 3, we present the results of ion emission
77 experiments with the fabricated arrays, where the arrays produced a current density 100 times
78 higher than that of conventional electrospray thrusters. Conclusions are presented in Sect. 4.

79

80 **2. Fabrication of nano-capillary emitter array**

81 **2.1. Nano-capillary emitter design**

82 Figure 2 presents a schematic of an electrospray thruster for high thrust density, consisting of a
83 nano-capillary emitter array, an extractor, and accelerator electrodes. In the nano-capillary
84 emitter array, the emitter pitch can be 5 μm , which signifies that the emitter density can be 4
85 million emitters cm^{-2} . The inner diameter of the tip of the capillary emitter can be less than 100
86 nm, as illustrated in Fig. 2, whereas the inner diameter of the previously fabricated capillary

87 emitters is approximately 700 nm.¹³⁾ The extractor is formed on a 1- μm -thick insulating layer,
88 signifying that the distance between the emitter and extractor is 1 μm , and its aperture is self-
89 aligned to each emitter. This small gap between the emitter and extractor enables lower-voltage
90 operation for ion emission, which implies that the emitter array can be used as an ultra-low
91 energy ion beam source.¹⁶⁾ However, low-voltage operation is not desirable for propulsion
92 applications from the viewpoint of the thrust T and specific impulse I_{sp} , defined as¹⁷⁾

$$T = \sqrt{\frac{2M}{q}} I_b \sqrt{V_b}, \quad (1)$$

$$I_{\text{sp}} = \frac{T}{\dot{m}g_0}, \quad (2)$$

93 respectively, where M is the ion mass, q is the ion charge, I_b is the ion beam current, V_b is the
94 net voltage through which the ion is accelerated, \dot{m} is the propellant mass flow rate, and g_0 is
95 the acceleration of gravity.

96 Conventional electrospray thrusters are operated at a high voltage of several kV to
97 obtain high thrust and specific impulse. However, our device cannot be operated at such a high
98 voltage due to breakdown between the emitter and extractor. Therefore, an accelerator electrode
99 can be added to enable high-voltage operation in future work. In our device, ionic liquid is
100 supplied from the back side of the array. It is known that an emitter electrode composed of
101 metal undergoes an electrochemical reaction with the ionic liquid, which leads to erosion of the
102 emitter.^{18,19)} To overcome this problem, it is effective to fabricate the emitter with an insulating
103 material and apply a voltage to the ionic liquid through a distal electrode located upstream of
104 the emitter.¹⁹⁾ In our fabrication, we used silicon nitride (SiN) as the emitter material, and the

105 distal electrode was fabricated on the back side of the emitter array, as illustrated in Fig. 2.

106 The nano-capillary emitter has an extremely narrow flow path of the ionic liquid,
107 which effectively increases the fluidic impedance. Fluidic impedance is associated with liquid
108 transportation,²⁰⁾ and high impedance inhibits the increase in the flow rate of the ionic liquid.²¹⁾
109 The impedance of the capillary under the assumption of Hagen–Poiseuille flow is expressed as

$$\frac{128\mu L}{\pi D^4}, \quad (3)$$

110 where μ is the fluid viscosity, L is the capillary length, and D is the capillary diameter, illustrated
111 in Fig. 1. Because the capillary diameter of the nano-capillary emitter is a fraction of that of the
112 previous emitter,¹³⁾ high fluidic impedance can be achieved, as it is inversely proportional to
113 D^4 .

114 The wettability of the capillary emitter is also an essential factor. The low wettability
115 of the emitter causes the ionic liquid to remain at the tip of the emitter because the edge of the
116 emitter tip prevents the liquid from wetting and spreading over the emitter surface. We
117 controlled the wettability of SiN by CHF₃ plasma treatment. CHF₃ plasma is commonly used
118 for etching SiO₂ in the reactive ion etching (RIE) process and is known to form a fluorocarbon
119 layer on the material surface.²²⁾ The fluorocarbon layer is expected to reduce the wettability of
120 SiN. Figure 3 presents images of the ionic liquid on a CHF₃-treated SiN film and untreated SiN
121 film. We used the ionic liquid of 1-ethyl-3-methylimidazolium dicyanamide (EMI-DCA),
122 which is often used for electrospray thrusters because ions tend to be emitted in the ion mode
123 instead of the droplet mode.²³⁾ After 1.5 μ L of EMI-DCA was dropped on each material, the

124 contact angle was calculated by the half-angle method. As illustrated in Fig. 3, the contact
125 angles of EMI-DCA were 87.2° and 37.5° for the CHF_3 -treated SiN film and untreated SiN
126 film, respectively. This result indicates that CHF_3 -treated SiN has lower wettability than
127 untreated SiN. Thus, we used CHF_3 -treated SiN as the emitter material.

128

129 **2.2. Fabrication process of nano-capillary emitter array**

130 Figure 4 presents the fabrication process of the nano-capillary emitter array. First, an Al layer
131 (100 nm) was deposited by sputtering on a Si wafer, which served to stop the deep reactive ion
132 etching (deep-RIE) process later. Thereafter, Ni conical emitters were formed on the Al layer
133 using the fabrication of a volcano-structured double-gate Spindt-type FEA, as illustrated in Fig.
134 4(a).^{14,24,25)} A thin SiN layer (50 nm) was deposited over the emitters and etched at the tip of
135 the emitters by the etch-back method, as illustrated in Fig. 4(b).²⁶⁾ Although a photolithography
136 process with 0.5 μm resolution is required for Ni conical emitter formation, an emitter capillary
137 diameter of less than 100 nm can be formed without a photolithography process using the
138 processes in Figs. 4(a) and (b). A SiO_2 layer (1 μm) was then deposited by plasma-enhanced
139 chemical vapor deposition as an insulator between the electrodes. The extractor was also formed
140 by the etch-back method for the sputtered Nb layer (200 nm) on SiO_2 , as illustrated in Fig. 4(c).
141 The emitter tip was uncovered by removing the SiO_2 insulating layer at the tip by buffered HF
142 wet etching, as illustrated in Fig. 4(d). After the Cr mask (200 nm) was formed on the back side
143 of the wafer, the ionic liquid reservoir was fabricated by the deep-RIE process from the back

144 side, as illustrated in Fig. 4(e). Finally, the ionic liquid flow path was formed by removing the
145 Al etch-stop layer and the Ni Spindt-type emitters with a wet etching process, as illustrated in
146 Fig. 4(f). It should be noted that the SiN layer was directly formed over the Ni cones to fabricate
147 the nano-capillary emitter, whereas in the previous fabrication process, a SiO₂ insulating layer
148 was also deposited on the Ni cones before the emitter electrode.¹³⁾ This direct emitter fabrication
149 shortened the entire SiO₂ fabrication process of the Ni emitters. Moreover, in this fabrication,
150 we used a minimal fab system for all photolithography processes and the deep-RIE process for
151 the ionic liquid reservoir, as illustrated in Fig. 4(e).^{27,28)} This system is suitable for multi-product
152 and low-volume manufacturing, such as for spacecraft devices.

153 Figure 5 presents scanning electron microscopy (SEM) images of the emitter array and
154 one emitter and extractor set. The emitter density reached 4 million emitters cm⁻² by fabrication
155 with a 5-μm emitter pitch. As illustrated in Fig. 5, the Ni cones were successfully removed, and
156 the nano-capillary emitter was fabricated. The inset of Fig. 5(b) presents the top-view image of
157 the nano-capillary emitter, where a 108-nm capillary diameter of the emitter was achieved.
158 SEM imaging demonstrated that the diameter of the emitter capillary formed by the etch-back
159 method varied depending on the emitter position in a wafer and the etch-back time of each
160 wafer. When the capillary diameters of 80 emitters in one wafer (Wafer A) were measured, the
161 average diameter was 258 nm with a standard deviation of 38 nm. Thereafter, we reduced the
162 etch-back time in another wafer (Wafer B) and measured the diameter of 65 emitters. The
163 results revealed that the average diameter was 167 nm with a standard deviation of 47 nm.

164 The diameter variation is caused by differences in the Ni cone height, resist thickness,
165 and resist etching rate in the etch-back process. Of these factors, the difference in Ni cone height
166 has a dominant effect on the diameter variation because the variations of the resist thickness
167 and etching rate are negligible. Therefore, by obtaining a uniform Ni conical emitter array, we
168 can achieve the desired capillary diameters within the range of the Ni cone's tip curvature and
169 base diameter by precisely adjusting the etch-back time.

170

171 **3. Ion emission experiment**

172 Figure 6 presents the experimental setup for the measurement of the ion emission current. The
173 measurement was performed in a vacuum chamber at a pressure of less than 1.0×10^{-3} Pa. We
174 prepared nano-capillary emitter arrays within a 300- μm diameter area that had a different
175 number of emitters: 10×10 , 20×20 , 40×40 , and 2,593 (maximum number of emitters with
176 5- μm pitch in a 300- μm diameter circle). These arrays were integrated within a half-inch wafer
177 as an independent emission area. Then, 0.1 μL of EMI-DCA was dropped on the back side of
178 the emitter array with a micropipette. Here, the flow rate of the ionic liquid was not actively
179 controlled. The ionic liquid was connected to a source meter (Keithley 2636A) through a 1-M Ω
180 resistor via the distal electrode on the back side of the array. A bipolar pulse voltage of 5 Hz
181 was applied to the extractor by the source meter (Keithley 2636A) through a 100-k Ω resistor.
182 The collector electrode for measuring the ion emission current was placed 1 mm downstream
183 of the emitter array. A 5-Hz bipolar pulse was also applied to the collector by another source

184 meter (Keithley 2657A), where the amplitude was fixed at 500 V and the polarity was always
185 the same as that of the extractor voltage.

186 It should be noted that the potential structure was opposite that illustrated in Figs. 1
187 and 2. In the electrospray thruster concept, the outermost electrode (extractor in Fig. 1 and
188 accelerator electrode in Fig. 2) is connected to the ground potential to accelerate ions to the
189 outside of the spacecraft. In contrast, in the present study, the distal electrode was grounded,
190 and bipolar pulse voltage was applied to the extractor. The reason for this was that the distal
191 electrode was common to all emission areas of the wafer, and we needed to apply voltage to
192 each emission area to investigate the emission characteristics independently. Since the collector
193 electrode was always more strongly biased than the extractor, the present potential structure did
194 not affect the results.

195 The currents of the emitter, extractor, and collector increased abruptly with the change
196 in voltage polarity even without ionic liquid because they were located close to each other like
197 capacitors. Therefore, we excluded the measurement data for the first 20 ms of the voltage
198 alternation to eliminate the high-frequency components, and the measurement range of the
199 current was set to 100 μA (accuracy of $\pm 0.025 \mu\text{A}$) in the experiments described below.

200 Figure 7 plots the onset voltage of ion emission as a function of the capillary inner
201 diameter of the emitter. Ion emission was performed using the multiple emission areas
202 integrated within the two wafers (Wafers A and B), as mentioned in Sect. 2.2. Here, the
203 capillary diameter in Fig. 7 was taken from the averaged values of five emitters randomly

204 selected from each array. The ion emission started at 61 V using the emitter array with a 124-
 205 nm capillary diameter. The largest capillary diameter in this measurement was 261 nm, and the
 206 ion emission started at 71 V. It should be noted that only data at 261 nm were obtained from the
 207 emitter array fabricated on Wafer A, while the other data were obtained from Wafer B. The
 208 values of the onset voltages for capillary diameters of 157 nm, 209 nm, and 261 nm were
 209 measured twice using the same array. The solid line in Fig. 7 was obtained from the theoretical
 210 onset voltage under the assumption that the tip of the ionic liquid had a parabolic shape
 211 corresponding to

$$V_s = \sqrt{\frac{\gamma r_c}{\epsilon_0}} \ln \frac{2d}{r_c}, \quad (4)$$

212 where r_c is the radius of curvature at the tip of the ionic liquid, γ is the surface tension (0.06127
 213 N/m at 292.96 K for EMI-DCA),²⁹⁾ ϵ_0 is the permittivity of free space, and d is the distance
 214 between the tip of the ionic liquid and the extractor, which was a flat plate ($d = 1,000$ nm).³⁰⁻³²⁾
 215 The radius of curvature was assumed to be equal to the inner radius of the capillary emitter.³³⁾
 216 The values of the experimental data were smaller than the theoretical values, likely because the
 217 radius of curvature was overestimated and the extractor was not entirely flat. Nonetheless, they
 218 were qualitatively consistent with the theoretical estimation.

219 Figure 8 presents the current density as a function of the voltage applied to the extractor.
 220 The amplitude of the applied voltage was increased from 0 to 90 V by 1 V. The current was
 221 averaged for four measurement points for each voltage pulse. This result was obtained using
 222 400 emitters arranged in a 20×20 array with 5- μ m pitch from Wafer A, where the current

223 density was calculated with an emission area of $100 \times 100 \mu\text{m}^2$. The positive ion emission
224 started at -72 V , and the positive current increased to $4.3 \mu\text{A}$ at -75 V . The negative ion emission
225 also started at 72 V , and the negative current reached $-1.3 \mu\text{A}$ at 77 V . Beyond 75 V of the
226 absolute value of the extractor voltage, the extractor current increased due to the interception of
227 emitted ions by the extractor, where the ions were emitted unstably, and leakage of ionic liquid
228 occurred. Nonetheless, no extractor current was detected at voltages in the range of $\pm(72-75)$
229 V , indicating that ions were emitted stably without leakage of ionic liquid.

230 Regarding the current density, the maximum positive value was 43 mA cm^{-2} , while
231 the negative value was -13 mA cm^{-2} . These current densities are approximately 50 and 9 times
232 higher, respectively, than those of the previously fabricated emitter array on the positive and
233 negative side,¹³⁾ and thus, more than 100 times higher than that of conventional electrospray
234 thrusters on the positive side.⁵⁾ Assuming that an accelerator electrode is integrated into this
235 array and the ions are accelerated by 1 kV acceleration voltage, the thrust density calculated
236 from Eq. (1) can reach 2.1 mN cm^{-2} for positive ion emission and 0.48 mN cm^{-2} for negative
237 ion emission. Here, the mass of EMI and DCA are 111 g mol^{-1} and 66 g mol^{-1} , respectively,
238 and both positive and negative ions are assumed to be emitted as singly charged ions. In the
239 case of positive ion emission, this estimation indicates that the thrust density is comparable to
240 or higher than that of other plasma thrusters.¹²⁾

241 Figure 9 illustrates the applied voltage of the bipolar pulse and currents of each
242 electrode as a function of time. We used 400 emitters arranged in a 20×20 array with $5\text{-}\mu\text{m}$

243 pitch from Wafer A. The amplitude of the applied voltage was increased from 0 to 72 V by 2
244 V at a repetition frequency of 5 Hz. After reaching the target voltage of ± 72 V, the bipolar pulse
245 voltage was continuously applied for approximately 20 s. The current was averaged for four
246 measurement points for each voltage pulse. The collector current of the positive and negative
247 ions started to increase at 11 s and 12 s, respectively, which indicated a delay of approximately
248 4 s from the time that the amplitude of the applied voltage became steady. This delay implies
249 that the ionic liquid did not reach the emitter tip when the voltage was initially applied, and
250 moved to the tip while the voltage was being applied. After the collector current of positive
251 ions peaked to 1.4 μA at 12 s, the current decayed and converged to 300 nA. The collector
252 current of negative ions was continuously in the range of 200–300 nA. It should be noted that
253 a small extractor current was detected due to the current measurement accuracy (± 0.025 μA).
254 Therefore, the extractor current could be regarded as 0 during the measurement, indicating that
255 the ionic liquid did not leak during operation.

256

257 **4. Conclusions**

258 In this paper, we fabricated a nano-capillary emitter array to increase the fluidic impedance for
259 stable ion emission without leakage of ionic liquid. The nano-capillary emitter was successfully
260 fabricated with a 100–300-nm capillary diameter that could be varied by adjusting the etch-
261 back time. SiN was selected as the insulating material of the emitter to suppress the degradation
262 of the emitter surface by electrochemical reactions. The SiN emitter was treated by CHF_3

263 plasma to prevent the ionic liquid from wetting and spreading.

264 After the fabrication, an ion emission experiment was conducted using EMI-DCA as
265 a propellant. The starting voltage of ion emission was in qualitative agreement with the
266 theoretical estimation. The maximum current density was 43 mA/cm^2 at a voltage of -75 V
267 applied to the extractor and -13 mA/cm^2 at 77 V , which is 10–100 times higher than that of
268 conventional electrospray thrusters. Assuming that an accelerator electrode is integrated into
269 this array and the ions are accelerated by 1 kV acceleration voltage, the thrust density can reach
270 2.1 mN cm^{-2} for positive ion emission and 0.48 mN cm^{-2} for negative ion emission. For positive
271 ion emission, this estimated thrust density is comparable to or higher than that of other plasma
272 thrusters. Finally, we obtained continuous ion emission in a certain voltage range without
273 current intercepted by the extractor, which indicates that ionic liquid did not leak during
274 operation.

321 **List of Figure Captions**

322

323 **Fig. 1.** Schematic of an internally fed electrospray thruster. A high-voltage bipolar pulse is
324 applied between the emitter and extractor electrode.

325

326 **Fig. 2.** (a) Cross-sectional and (b) top views of a high-density emitter array together with
327 extractor and accelerator electrodes. Nano-capillary emitters with 5- μm pitch are fabricated
328 within several 100 μm diameters of the ionic liquid reservoir. The extractor aperture is aligned
329 with each emitter to extract ions while the accelerator aperture is of the same order as the
330 reservoir diameter to accelerate the extracted ions. Note that the voltage is not directly applied
331 to the emitter but to the distal electrode.

332

333 **Fig. 3.** Contact angles of EMI-DCA on (a) SiN film treated by CHF_3 plasma and (b) untreated
334 SiN, where 1.5 μL of EMI-DCA was dropped on each material. These contact angles were
335 calculated by the half-angle method.

336

337 **Fig. 4.** Fabrication procedure of the nano-capillary emitter array. (a) First, a thin Al layer was
338 deposited on the Si wafer, and Spindt-type Ni emitters were formed on it. (b) After the
339 deposition of a thin SiN layer over the emitters, the SiN layer at the tip of the emitters was
340 etched using the etch-back technique. (c) SiO_2 and Nb were deposited in series. The extractor

341 aperture was also formed similarly by the etch-back technique. (d) Removing SiO_2 by the BHF
342 wet etching process opened the emitter tip. (e) After protecting the outside of the emitter array
343 by photoresist and forming the Cr mask on the back side of the wafer, the deep-RIE process
344 was performed. (f) Finally, the Al layer and the Ni emitters were removed.

345

346 **Fig. 5.** SEM images of (a) the 5- μm pitch nano-capillary emitter array and (b) one set of an
347 emitter and extractor. The inset in (b) presents the top view of the emitter.

348

349 **Fig. 6.** Schematic of the experimental setup for measurement of the ion emission current.

350

351 **Fig. 7.** Onset voltage of ion emission (open squares) versus capillary diameter. The solid line
352 follows the theoretical onset voltage expressed as a function of the curvature radius at the tip of
353 the ionic liquid (see Eq. (4)), which is assumed to be equal to the capillary radius here.

354

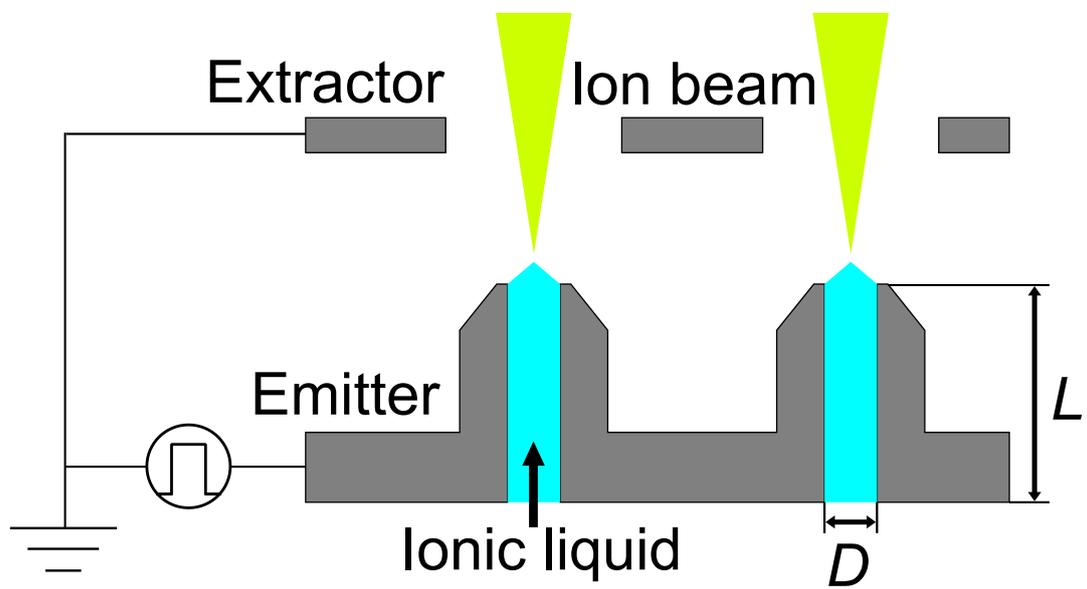

355 **Fig. 8.** Current and the current density of the emitter (open circles), extractor (open squares),
356 and collector (open triangles) as a function of the voltage applied to the extractor.

357

358 **Fig. 9.** (a) Applied extractor voltage, (b) collector currents of positive ions (open circles) and
359 negative ions (open triangles), and extractor current (open squares) as a function of time.
