## Doctoral Dissertation

The Chinese urban economy and ASIE manufacture firms' activity: an empirical research based on the micro data

## Acknowledgement

All my achievement should be attributed to the love and friendship from my parents,friends, supervisors and Yokohama National University. Especially I am significantly motivated by the open and free academic atmosphere here which I never experienced before.

During the six years as PhD student in YNU, I am indebted to my supervisors, Professor Taro Akiyama, Masahito Kobayashi and Yoshiaki Omori. Especially I got many inspirations and encouragements from the tutoring of Professor Taro Akiyama, who support me to persist in my research into the topic which I really enjoy. Although I have experienced nearly 6-years long non-academic work in China, I regained my decisiveness and resilience to become a researcher in the future.

Graduate school of international social sciences of YNU is a prestigious research establishment in Japan, where I got many inspiring lectures. Besides activating and updating my stock of economics knowledge, I am enlightened in the field of statistics and econometrics that play the pivotal role in the empirical economic analysis. No one else ever thoroughly and clearly gave me the inspiration to dive into these two fields as in YNU.

Also I owe my new friends in Japan, who help me to better integrate into a different lingual and cultural circle. Without them I would not have overcome the anxiety and rootlessness in the first few years when I came here. Moreover outside the campus I deeply experience the differences between a open, inclusive and civilized society from an authoritarian society. Not only psychically people are also free to boast their own dreams and minds, which nourish the whole nation to advance in the development of wisdom and well-being.

Last but not the least, compared with the knowledge and skills, moral and integrity play more import roles in the human world, which are also the ethics source of economic thoughts. And I will uphold these virtues to contribute for the well-being of our world.

## Acronyms

ASIE：refers to China＇s Annual Survey of Industrial Enterprises．As of July 2021，1998－2013 period database is semi－overt for public．

CNKI：refers to China National Knowledge Infrastructure，a key national research and information publishing institution in China with the website as www．cnki．net．

EPO：refers to European Patent Office

NBS：refers to Chinese national bureau of statistics

HMT：refers to Hong Kong，Macau and Taiwan

LQ：refers to location quotient
$C D$ ：refers to cross－section dependence

CSMAR：refers to China Stock Market \＆Accounting Research

CODS：refers to China Organization Data Service，a affiliate to SMAR

SMAR：refers to State Administration of Market Regulation or 国家市场监管管理总局，a Chinese government agency

MAUP：refers to Modifiable Areal Unit Problem
$S A C$ ：refers to spatial autoregressive combined model

SDEM：refers to Spatial Durbin error model

## Glossary

China／Chinese：refers to Chinese mainland not including Hong Kong，Macau and Taiwan．
State－owned：means that Chinese central／local governments full－fill the responsibility of the only share－ holder／the largest percentage shareholder．

Collective－owned：means the entity that belongs to all the members of a group，usually a town or a village．The collective－owned firms are affiliated to a town／village government．

PATSTAT：refers to 2020 spring edition global patent database of version 5.15 by European Patent Office
TIANYANCHA：refers to 天眼查，a big data technology service company with a vast repository of Chinese enterprise information．

QICHACHA：refers to 企查查，a big data technology service company with a vast repository of Chinese enter－ prise information．
WANFANG：refers to 万方数据，an affiliate of the Chinese Ministry of Science \＆Technology，who provides access to a wide range of database resources．

## Chapter 1

## Introduction

Since 1990,due to deepening reform and opening up policy, Chinese enterprises have came through tremendous all-around changes during this process. Especially,due to the state-owned firms reform originating from 1992,the planning-economy style factories $\ddagger$ were mostly shut down, merged, split or privatized.In addition, more and more HMT and foreign enterprises launched in Chinese market by sole investment or joined investment with Chinese peers. Accordingly, western corporate governance system and R\&D system were gradually embedded in the economy plagued with Soviet Union economic system.From the Figure 1.1, we can have a glimpse about the overall evolution of the Chinese industrial enterprises during year 1998-2013.

In the second chapter, I will expand on the databases used in this paper, including ASIE, and patent databases of CNKI and PATSTAT. For any scholar interested in Chinese enterprise analysis, they have to face up to the problems with ASIE such as default value, clarifying blurred firms' identities, integrating scatted yearly databases as one, linking with other databases and handling abnormal values etc. Thanks to the data science, these obstacles have been mitigated and fixed somewhat. Meanwhile, using the applicant names, I have scratched the unique ID number assigned by government for nearly all the firm applicants in SIPO's patent database,which enable us to match the ASIE and CNKI.

Nevertheless, CNKI patent database only contains very limited information about the application record, where citation information is not publicized. To complement CNKI database, I resort to the PATSTAT by EPO(European Patent Office). PATSTAT consists of all-around information, however it is in different languages other than Chinese. Thereafter, I resort to Google Patent search engine to scratch all the Chinese names for the Chinese organisational applicant in PATSTAT. The linkage among these 3 database brings about the synergistic effect that more thorough analysis can be carried out.

[^0]

Figure 1.1: Ownership share transition

In the third chapter, I adopted two categories' indices respectively based on discrete space and continuous space pre-requisition to measure the agglomeration. Especially to embrace the location factor in a continuous space I scraped the geographic information for all the enlisted ZIP codes in ASIE, which makes the spatial econometric tools available in this paper.In addition,the relation between the firm size with the externalities are estimated in the city. And spatial weights matrices are constructed to introduce a spatial econometric analysis frame. Thereafter spatial spillover effect by Machiavellian and Jacobian externalities are estimated alongside with the basic panel models for the ASIE data. Especially different from basic models the spatial econometric models disentangle the direct effect from the indirect effect.

In the fourth chapter, co-patenting and citation networks are constructed based on the result of the second chapter. Moreover yearly descriptive statistics and visualization are achieved. Based on the derived results I will probe into the co-patenting and citation networks' influences on firms' performance. Especially the firm level Farrell production efficiency is estimated with adoption of a stochastic frontier model. In addition effects of each node's role is estimated with respect to efficiency, wage level and innovation performance.

## Chapter 2

## ASIE and the patent database

### 2.1 Introduction

The linkage of ASIE database with other database about Chinese industrial firms has always been a attractive but thorny domain for every researchers concerned with the empirical analysis about Chinese manufacturing sector. Due to the intricate composing process and shift of statistical system ASIE are also entangled with identification issues across different years. M, Eberhardt, et al.(2011) match both SIPO and USPTO patents of invent filed between 1985-2006 to a subset of about 20,000 firms in ASIE with the identification numbers recorded in Oriana, where a faction of ASIE firms are recorded with latin letter names, Chinese names and ids(i.e. id of ASIE). Other than the identifiers, J. Dang and K. Motohashi(2015) match SIPO's invent data with ASIE between 1985 to 2008 by means of the firms' names. Likewise enlarging the scope to 3 types of patent, Z. Xie and X. zhang(2014) match SIPO with ASIE between 1985 to 2009. Zl. He, et al.(2018) strengthened the method with fuzzy matching firms' names and increase the matched result for 3 types of patent between 1985 to 2009 .

Except M. Eberhardt, et al.(2011) all other researchers focus on the firms' names to bridge the databases. Nevertheless modification of business registry info including names is very common in the long time span in China. So it is certain that the patenting fact must outnumber the matched results with names. Moreover each Chinese firm has its own unique identifier(i.e. organization code), which is also recorded in ASIE as id. With the social credit system developing firm's unique identifier can be easily accessed through the business registry query website like Tianyancha.

Meanwhile the non-Chinese firm names are the main obstacle for researchers to match the ASIE with patent
database by EPO and USPTO．For those applications overseas filed by Chinese firms，it is very difficult to identify the Non－Chinese names（ M，Eberhardt，et al．2011）．And this issue can also be settled with the help of Google patent which align the patent application globally based on the patent family．Therefore it is very reasonable to trace the application overseas back to their domestic counterparts and snatch their Chinese names．In order to match these retrieved complementary data with the ASIE，web scraper and string fuzzy match algorithm are heavily utilized here．

Besides linking to ASIE，identifying the applicants unenrolled in ASIE are also achieved as the construction of co－patenting and citation networks are also target here，because both of these networks involve more appli－ cants out of the reach by ASIE

## 2．1．1 ASIE database

According to NBS，ASIE＇s involves all the state－owned enterprises and the non－state－owned enterprises with turnover over 5 million Chinese yuan（ 20 millions Chinese yuan since 2011）．And the industries can be divided into 3 subgroups of mining，manufacturing and public services（water，electricity and gas）．${ }^{2}$ And by now the available database for public is based year 1998－2013．3

Due to the authority and continuity of this database＇s composition by NBS，ASIE is more frequently utilized to probe into the micro level issues with Chinese manufacturing sector compared with the database such as the small and medium sized enterprise database by CSMAR．As to the adoption of this database，the most mentioned problems can be summed up as bellow：

1．Non－continuous observations across different years．Some enterprises are missing halfway in this time span as a result of bankruptcy，merge \＆acquisition，public－owned firm＇s reform，slump of business and even missing response．Especially most research only used the database from 1998－2007，which can be attributed to the comparatively mature methodology developed by Loren Brandt，et al（2011）to integrate 1998－2007 databases．On contrary compared with the database before 2008，post－2008 database seemingly experienced drastic amendment of firm samples．

2．Inconsistency of the variables across different years just as showed by table 2．1．Among the these variables the ID variable is key to identify the unique firms．Nevertheless ID information is missing in year 2008．Also variables closely related this research like new product output（新产品产值），total intermediate input（中间投入）and payable wages（应付工资）are only available in some years．Specifically new product output are only

[^1]available in year 1998－2007， 2009 and 2010；payable wages is missing in year 2010；total intermediate input is missing since 2008.

Table 2．1：Yearly counts of observations and variables

| Year | 1998 | 1999 | 2000 | 2001 | 2002 | 2003 | 2004 | 2005 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Count of observations | 165,116 | 162,033 | 162,885 | 171,256 | 181,557 | 196,222 | 279,092 | 271,835 |
| Count of variables | 105 | 105 | 106 | 103 | 95 | 88 | 150 | 140 |
| Year | 2006 | 2007 | 2008 | 2009 | 2010 | 2011 | 2012 | 2013 |
| Count of observations | 301,961 | 336,768 | 411,212 | 473487 | 348,536 | 303,392 | 310,832 | 344,882 |
| Count of variables | 130 | 140 | 72 | 72 | 80 | 98 | 88 | 97 |

3．Unstable variable＇s definition across the period．The most obvious one is the ID information，which refers to unique organization code（i．e．组织机构代码）issued by NACAO affiliated to SAMR And to certify the code a certification rule was defined by official regulation GB 11714－1997 and another amended version in 2007. Except the occasion that registered content need to be modified，the code will stay unchanged for a unique legal person．So the recorded ID starting with AH，CH，BC，BD，BJ，BT，GX，etc are found to be unverifiable dummy IDs which cannot be linked to other years＇entries．Moreover the definition of wage payable and welfare benefits payable were modified based on the amended version of accounting standard issued in year 2006．According to the newer version，wage payable and welfare benefits are combined as payroll payable alongside with social security expenses，education expenses，labor union fees，etc．Therefore payroll payable covers more than before．

4．Price deflation．As the responses by sample firms are based on values at the responding time point，the price level are not unified．Different from Loren Brandt（2011），I use the yearly composite PPI（i．e．producer price index for industrial products）publish by NBS with year 1998 as base level 100.

## 2．1．2 Patent database

The patent data involved here includes all the openly publicized invent applications documented at SIPO（i．e． China＇s state Intellectual Property Office）and overseas．They are all filed in by Chinese firms and universities alongside with other bibliometrically related applications by other types of organization．And the time span is set as the period with the ending date as December 31th 2013 according to the application date filed with．

[^2]Because the first patent protection law of China was promulgated in 1985, the first patent filed in can be traced back to 1985 and the starting date is set as January 1st 1985.

Data source here contains 3 openly accessible sources: search engine of CNKI, PATSTAT of EPO(i.e. European Patent Office) and search engine of Google patent. And they have their own obvious strengths and shortcoming as bellow:

Table 2.2

|  | Strengths | Shortcomings |
| :--- | :--- | :--- |
| CNKI Patent | 1. It is downloadable in batch; <br> 2. All applicant name are in Chinese which can <br> be matched with ASIE more easily; <br> 3. More frequently updated. | Only information of patent title, inventor name, <br> applicant name, application data and publication <br> date can be downloaded in batch. |
| PATSTAT | 1.The citation relation is discreetly recorded <br> among the publicized patent application glob- <br> ally; <br> 2. All around information related to the appli- <br> cation are listed. | 1. Nearly all Chinese applicants' name are in <br> non-Chinese messily and non-uniformly, which <br> make it impossible to be linked with ASIE di- <br> rectly; <br> 2. Nationality and type of applicant are not |
| Google Patent | 1.Frequently updated all-round information are <br> exposed altogether with the scanned original <br> application document ; <br> sorted up thoroughly. | 1. It cannot be downloaded in batch; <br> 2. The information are scatterd and not sorted <br> out. |
| the different applicaton IDs, which make it con- |  |  |
| venient to trace back to the applicant names in |  |  |
| its native language. |  |  |

### 2.2 Methodology

As the linkage is set up from scratch based on very tedious and maze-like process such as data wrangling, fuzzy match and visualization, it is very necessary to outline the process beforehand as figure 2.1 shows. All the operations I take is aimed to attach the organization IDs to all the firm applicants, which can be linked easily across different databases related to Chinese firms. Especially fuzzy match algorithm is a frequently utilized technique here to link firms across databases. It is introduced by Levenshtein(1965), which is the minimum number of single-character edits (insertions, deletions or substitutions) required to transform one word to another word. Therefore the Levenshtein distance between two strings a and b (of length $|a|$ and $|b|$

respectively）is given by $\operatorname{lev}(a, b)$ where

$$
\operatorname{lev}(a, b) \equiv\left\{\begin{align*}
|a| & \text { if }|b|==0,  \tag{2.2.1}\\
|b| & \text { if }|a|==0, \\
\operatorname{lev}(\operatorname{tail}(a), \operatorname{tail}(b)) & \text { if } a[0]=b[0], \\
1+\min (\operatorname{lev}(\operatorname{tail}(a), b), \operatorname{lev}(a, \operatorname{tail}(b)), \operatorname{lev}(\operatorname{tail}(a), \operatorname{tail}(b))) & \text { otherwise }
\end{align*}\right.
$$

And the tail of any string $a$ is the substring without the first character of $a$ ，and $a[n]$ is the $n t h$ character of a counting from 0 ．So it needs $|a| \times|b|$ steps to get the Levenshtein distance between them．To clarify this obscure definition a practical example about two Chinese strings＂核工业部北京核仪器＂and＂中国核工业北京核仪器＂ is listed as table 2.3 shows．The calculations starts form $[0,0]$ to $[9,10]$ in the matrix and the derived distance is 3 ，which implies these two names probably refer to the same establishment．This algorithm is especially sensible for Chinese misspelling and Chinese abbreviation such as＂湖南省醴陵市太山出口鞭炮烟花制造有限公司＂，＂醴陵市白兔潭大山花炮厂＂and＂醴陵市太山出口烟花制造有限公司＂all refer to the same establishment． And＂湖南省醴陵市白兔潭＂is the location of this firm，which differs in each response alongside with＂大＂as a misspelling of＂太＂．Inconsistent names can be attributed to formally modification for business registry or just abbreviation at the typewriter＇s will．To complement the Levenshein distance，names like＂醴陵市白兔潭大山花炮厂＂cannot be verified in open－accessible business registry query website like Tianyancha．So it can be concluded that this name is just a misspelling．

Table 2.3

|  | loc | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
| :---: | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| loc | ＂＂is null | ＂＂ | 中 | 国 | 核 | 工 | 业 | 北 | 京 | 核 | 仪 | 器 |
| 0 | ＂＂ | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
| 1 | 核 | 1 | 1 | 2 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 |
| 2 | 工 | 2 | 2 | 2 | 3 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
| 3 | 业 | 3 | 3 | 3 | 3 | 3 | 2 | 3 | 4 | 5 | 6 | 7 |
| 4 | 部 | 4 | 4 | 4 | 4 | 4 | 3 | 3 | 4 | 5 | 6 | 7 |
| 5 | 北 | 5 | 5 | 5 | 5 | 5 | 4 | 3 | 4 | 5 | 6 | 7 |
| 6 | 京 | 6 | 6 | 6 | 6 | 6 | 5 | 4 | 3 | 4 | 5 | 6 |
| 7 | 核 | 7 | 7 | 7 | 6 | 7 | 6 | 5 | 4 | 3 | 4 | 5 |
| 8 | 仪 | 8 | 8 | 8 | 7 | 7 | 7 | 6 | 5 | 4 | 3 | 4 |
| 9 | 器 | 9 | 9 | 9 | 8 | 8 | 8 | 7 | 6 | 5 | 4 | 3 |

## 2．3 ASIE raw data process

ASIE can be traced back to 1998，so it is very vulnerable to loose data entry，modification of business registry， amendment of statistical regulation and some subtle historical reasons．And the key clue to string these sparse observations is to attach the verifiable organization code．

Based on existing data entries，one verifiable organization code can be linked to one or multiple names but not vice versa．So for those entries only containing the IDs，their firm names can be easily retrieved from other years＇proper and intact entries．And the unmatched IDs can be queried in Tianyancha，Qichacha，etc．As to the firm names without IDs，besides merging with the intact entries and business registry queried result， fuzzy match alongside with comparison of address，representative name，industry sector code and telephone number is heavily used because the misspelling and abbreviation seriously flaw the firms＇identity．

Before the fuzzy match，a preliminary trim of firm names is needed as they are just auxiliary to identify a estab－ lishment．And these auxiliary information or substrings can be categorised into punctuation ${ }^{5}$ ，administrative division level，registry types，ownership，which can be exemplified as bellow：

And also replicates is another obstacle encountered．The observations with no entry into variables of interest are deleted．For those with different address，they are treated as different plants belonging to the same firms． Trough this process a unbalanced panel data with organization codes as unique identifiers can be achieved

[^3]Table 2.4

| administrative division level | 省，市，区，县，乡，自治 |
| :--- | :--- |
| registry info | 厂，公司，总公司，分公司，集团 |
|  | 股份有限公司，有限责任公司，有限公司，集团 |
| ownership | 国营，集体，私营，中外合资，中日合资，中美合资 |

with the yearly counts as tables 2.4 and 2.5 show．Especially extracted from these $4,224,492$ observations 796， 833 firms have been enlisted at least once in ASIE．And 124， 751 firms are just enlisted once alongside with 20， 064 firms outliving these 16 years．

Table 2．5：Yearly count of observations

| year | Freq． | year | Freq． |
| :--- | :--- | :--- | :--- |
| 1998 | 164,947 | 2006 | 301,851 |
| 1999 | 161,946 | 2007 | 336,670 |
| 2000 | 162,800 | 2008 | 411,823 |
| 2001 | 168,946 | 2009 | 320,522 |
| 2002 | 181,481 | 2010 | 310,581 |
| 2003 | 196,154 | 2011 | 302,582 |
| 2004 | 276,283 | 2012 | 311,308 |
| 2005 | 271,772 | 2013 | 344,826 |
| Total | $4,224,492$ |  |  |

Table 2．6：count of firms grouped by times of occurrence

| $\#$ | Freq | Percent | $\#$ | Freq | Percent |
| :--- | :--- | :--- | :--- | :--- | :--- |
| 1 | 124,751 | 16 | 9 | 34,486 | 4.33 |
| 2 | 120,444 | 15 | 10 | 35,850 | 4.5 |
| 3 | 110,024 | 14 | 11 | 21,409 | 2.69 |
| 4 | 60,314 | 7.57 | 12 | 16,930 | 2.12 |
| 5 | 73,467 | 9.22 | 13 | 18,795 | 2.36 |
| 6 | 48,628 | 6.1 | 14 | 7,863 | 0.99 |
| 7 | 55,065 | 6.91 | 15 | 10,007 | 1.26 |
| 8 | 38,736 | 4.86 | 16 | 20,064 | 2.52 |
| Total |  | 796,833 |  |  |  |

## 2．4 Construction of co－patenting network

## 2．4．1 Linkage of ASIE and CNKI patent

Data source here is based on the published 1985－2013 invent patent by SIPO through the CNKI patent platform． And all the applications with applicant names containing＂公司＂（i．e．firm），＂厂＂（i．e．factory）and＂大学＂ （i．e．university）are retrieved．Compared with the published database by SIPO，the CNKI patent is a online query database．And it can be verified that the records are more frequently updated in CNKI，which means the newly publish ones can be included in time．By fuzzy matching firm names with ASIE and query into the
business registry database，organization codes can be attached mostly to the firm applicants of the CNKI＇s data．

Another difficulty entangled is to attach the IDs with the firms names only used in 1980s and early 1990s． As Chinese state－owned and collective－owned have gone through dramatic reform and restructure in 1990s， overwhelming modification of business registry handicap the effort to retrieve the IDs for these firms．To address this issue，organization database of WANFANG ${ }^{6}$ is introduced here as it hold plentiful organization evolution info．So the former names recorded in CNKI can be connected to their existing heirs according to WANFANG．The remained few unmatched ones can be either linked manually or just labelled with pseudo identifiers．For example＂江汉石油管理局总机厂＂is the predecessor of＂中石化石油机械股份有限公司江汉机械厂＂，so these two names are taken as the same firm．

Compared with other researchers＇matched results，a overview can be listed as bellow．Moreover a specific break down can be referred to table 3．2．

Table 2．7：Compared with existing match results ${ }^{7}$

|  | Period |  | Matched Result |  |  |
| :--- | :--- | :--- | ---: | ---: | ---: |
| Authors | ASIE | SIPO | \＃of ASIE Assignee | Identified \＃of Invent | Matched \＃of Invent |
| Eberhardt | et al． | $1999-2006$ | $1985-2006$ | 1,219 | 405,180 |

## 2．4．2 Co－patenting network

Based on the result of linking ASIE to CNKI，co－patenting refers to the application by over one applicants， which can be distinguished by applicants names that contain semicolons（i．e．；）．So applications like CN201010563877 applied by＂河海大学；江苏省交通规划设计院有限公司；南京河海科技有限公司＂are co－ patents．And there is a co－patenting network as figure 4.3 shows：

With parsing all applicants＇names，application containing semicolons are all divided into applications that

[^4]

Figure 2.1
one application ID attaches to one applicant name．And it still needs discretion with the the parsed result． For the case of application ID $C N 93119522.5$ that the applicant name is＂广西中医学院；龙胜各族自治县轻工业局猕猴桃制品厂；苏必忠＂，one parsed result is a person＇s name＂苏必忠＂．And in the case of application ID $C N 200910025687.2$ with the applicant name recorded as＂江苏省交通规划设计院有限公江苏省长江公路大桥建设指挥部；中国人民解放军理工大学＂，one extremely lengthy parsed result is＂江苏省交通规划设计院有限公江苏省长江公路大桥建设指挥部＂．And it can be inferred that it is a typo of＂江苏省交通规划设计院有限公司；江苏省长江公路大桥建设指挥部＂．As most Chinese names＇lengths are less than 4，individual applicants can be parsed out easily．As of the typos，all the string length outliers are checked manually．

After the data wrangling and parsing，fuzzy matching with ASIE and inquiry into Tianyancha are carried out．Except those firms only existing in 1980s and early 1990s，nearly all firms are attached with their IDs． Thereafter the edge lists with IDs are sorted out．A brief overview of the linkage result is just as table 6.1 and table 6.2 show in the appendix．And among the total count of 914,591 invention patents， 782,227 can be matched with ASIE enlisted firms which mounts to 70,420 ．Within the constructed co－patenting network， 6，910 out of 22,795 net nodes are ASIE enlisted firms．

## 2．5 Construction of citation network

## 2．5．1 Linkage of ASIE and PASTAT patent

Data source here contains PATSTAT Version 5.15 and Google patent．And the linkage focus on the patent applications recorded in the citation documents．Moreover the linked citation records here is centering on the Chinese firms，which means that at least one node of a citation link is a Chinese organization and neither node is individual．Furthermore invent，design and utility are taken in consideration，as citation between different types of patent is not uncommon．According to the catalogue of EPO citations have different origins，and only

[^5]citations that are introduced by applicants with publicized verifiable application IDs are adopted here．Those citations with unique citing and cited $D O C D B_{-} F a m i l y \_I D s$ are taken as one effective citing linkage，as all the applications labelled with same $D O C D B_{\_}$Family＿ID refer to the same technology content．

The most prohibitive matter with adopting PATSTAT＇s Chinese applicatons is that nearly all the Chinese applicants＇name are in non－Chinese languages．Moreover same firm＇s name may varies dramatically across different applications such as＂HUWAEI TECHNOLOGIES CO．，LTD．＂，＂KHUAVEJ TEKNOLODZHIZ KO．， LTD．＂and＂HUAWEI TECHN CO．，LTD．＂．Actually all these names refers to Huawei Technologies Co．，Ltd（i．e．华为技术有限公司）．Nevertheless＂huawei techniques co．，ltd．＂refers to a Taiwan＇s firm＂华威科技股份有限公司＂． Obviously the non－Chinese translations can not keep all the nominal information such as tones．Therefore it is quite unreliable to adopt the back－to－Chinese translation to identify the firms．

Secondly EPO doesn＇t label the nationality for all the applicants．And those applicants with applicants filled in China National Intellectual Property Administration（i．e．SIPO）have high propensity to be Chinese．Therefore retrieving the original Chinese names recorded in the documented files is the most convincing and reliable way to identify them．Meanwhile Google patent search engine is open－accessible and all－around maintained which make it possible to retrieve the Chinese names．

Thirdly，identifying non－Chinese applicants is another issue，although EPO has made some but not enough efforts．For example，＂via technologies，inc．＂，＂weisheng electrionic co．，ltd．＂and＂vasion electronics co．，ltd．＂ are taken as different companies in PATSTAT．Nevertheless，they refer to the same firm＂VIA Technologies＂ in Taiwan．Similar mistaking can also be exemplified by＂sumitomo electric k．k．＂and＂sumitomo electronic industries，ltd．＂．

To solve the mentioned three defects，I resort to the Google patent for Chinese character names of applicants with nationality of China and Taiwan as well as English names of other countries＇applicants．Then as what is done with CNKI，the organization codes are attached．With regards to other countries＇applicants，their English names are used to identify same firm across different applications alongside with the PATSTAT Standardised Names．Even though fuzzy match can detect misspelling and abbreviation，it cannot be assured that all the identification can be soundly finished．For the linkage between likes of＂Orange $S A$＂and＂France Telecom S．A．＂，fuzzy match is totally powerless．Because France Telecom S．A．initiated to rebrand them as Orange S．A．

After closely manual check with non－Chinese applicants，a sketch of citation networks centering Chinese firms surface here．Among these citation links same－directed links between same applicants as well as same $D O C D B_{-}$Family＿IDs are abundant and taken as one effective link．Consequently it is very easy and pleasant to link the whole network to ASIE through the organization codes．And there are 316，785 patents embedded in this network out of which 115,456 are applied by 17,684 Chinese firms．Moreover 8,382 are ASIE enlisted firms．The specific result of nationalities of applicants are listed as tables 3．3，3．4， 3.5 and 3．6．

As to the citations between different countries, tables $\sqrt[8]{8}$ bellow give a ranking result about the nationalities of applications citing Chinese ones and the nationalities of those cited by Chinese ones respectively. Obviously US, Japan, Taiwan, South Korea and Germany maintain the most active interactions with China. A detailed breakdown of yearly nationalities shift can be traced in the tables of 6.3, 6.4, 6.5 and 6.6.

### 2.6 Summary

With the adoption of techniques from data science and taking the organization codes as the unique identifiers longitudinally across different databases, an enlarged linkage between ASIE and SIPO's database is achieved for a longer time span. Compared with the existing linkage result, all the data sources can be checked online. Moreover the ASIE database from 1998-2013 are more integrated by the unique organization codes and the linked results are prolonged to year 2013 which covering the early stage of patent application outburst since 2009, which causes at least doubled matched records.

Although patent citation analysis has been gaining considerable traction over the past few decades, micro level analysis about China are mostly limited to the context of patents themselves. There is no open published data bridging with other micro-level databases. The matched result here can fill the blank somewhat. Especially Chinese organization's identifying issue across different lingual contexts is somewhat tamped. The linked result can give a new insight into the technical progress rooted in firm's performance.
${ }^{8}$ country codes are in accordance with ISO 3166 code

## Chapter 3

## Manufacture sector geographic distribution and its influence on firm size in China

### 3.1 Introduction

Not only Geographic scientist, but also economists are attracted to the geographic distribution,especially the agglomeration phenomenon.Nevertheless,researchers have reach a deterministic conclusion to measure the extent of the agglomeration, which can be observed in different perspective.

Duranton and Overman(2002) argued that a satisfactory spatial agglomeration measurement should have the following properties:(1)be comparable across industries,(2)control for overall agglomeration trends across industries,(3)separate spatial concentration from industrial concentration,(4)be unbiased with respect to the degree of spatial aggregation,(5)admit a clear statistical significance test.

Combes et al. (2008, Chapter 10) and Kominers (2007) provide three other three additional properties:(1)be unbiased with respect to arbitrary changes to industrial classification;(2) be computable in the closed form from accessible data, and (3) be justified by a suitable model.

As far as now,agglomeration measures can be sub-grouped into 2 categories:model-based measurement and axiomatic-approach-based measurement. The first group rely on the assumption that each location is discrete and equidistant spatial units. The second group take the distance between each firms into consideration, with taking firms' location in a continuous space. Obviously the second group are independent of the administrative boundaries and closer to the reality, but much more demanding on the data and very hard to grasp mathematically.In the next section I will give a introduction about these two groups' indices utilized in this
paper.
Cecile Gaubert(2018) establish a equilibrium model of heterogeneous firms that freely mobile within a country and can choose the size of the city where they produce. Especially the labour force size in a given city can bring in positive externalities and mounting pressure for raising wages as the land supply is limited. Therefore firms sort across cities of different sizes in order to maximise their profits. In this process city labour size's relation with the firm's employee scale and profit is modelled.

Kim (1995) and Holmes and Stevens (2002) find a positive correlation between industrial agglomeration and plant size both across and within manufacturing industries by using plant-level data in the United States.

Dongya Li , et al.(2011) identified that industrial agglomeration has a positive and statistically significant causal impact on firm size through the instrumental variable estimation based on the ASIE data from 1998-2005.

Based on the discrete agglomeration results, a spatial econometric frame is adopted here to probe into the spillover effect about the agglomeration on firm size among the neighbouring cities.

### 3.2 Methodology

## Location Quotient indices(LQ indices)

The discrete agglomeration indices are very charming for policy-makers, who are keen on making regional policies for districts, cities, provinces or countries. Nevertheless,these indices are clumsy with handling the data within a specific space unit. In addition, all discrete agglomeration indices fail to address the Modifiable Areal Unit Problem(MAUP). The MAUP make an a discrete agglomeration index awkward to cope with the agglomeration phenomenon across different administrative regions.

The location quotient can be used to see whether the employment of a specific industry is above or bellow the average overall. The LQ offers the opportunity to compare industries which differ in size because of the calculation using the shares on the magnitudes (Vgl. FIGUEIREDO, O.; GUIMARAES, P; WOODWARD, D. 2007). The LQ for the industry A in subregion i can be calculated bellow, where the superscript N bellow means the whole region.

$$
\begin{equation*}
L Q_{i}^{A}=\left(E_{i, A} / E_{i}\right) /\left(E_{N, A} / E_{N}\right) \tag{3.2.1}
\end{equation*}
$$

And $E_{i, A}=$ Industry A's employment in subregion i, $E_{i}=$ Overall employment in subregion i, $E_{N, A}=$ Industry A's employment nationally, $E_{N}=$ Overall employment nationally.
The drawbacks of the LQ indices are also obvious:1.LQ arbitrarily take unit one as the cut-off value to determine whether a agglomeration exits in a region, which is always questionable because this industry probably does not stick out at all compared with other industries. 2. LQ cannot solve the MAUP problem.3.LQ does not take the firms' size into consideration, a single firm's extremely big size can seriously affect the meaning of the LQ indice. To cope with these drawbacks,several enhancements have been applied to the LQ.

Firstly,Moineddin,Beyene and Boyle (2003) suggested a testing method for significance of LQ's result,with the assumption that: (1) in a subregion i, each employee's choice about whether to work for industry A or not follows a Bernoulli distribution with parameter $p_{i, A}$ independently; (2) for a subregion i beholding $E_{i}$ 's workers, the outcome number of being engaged in industry A is in a binomial distribution(i.e. it is asymptotically a normal distribution, as $E_{i}, E_{i} \times p_{i, A}$ and $E_{i} \times\left(1-p_{i, A}\right)$ are large enough;(3) the distribution of each subregion is independent. Then by means of delta method, the variance of $L Q_{i}^{A}$ can be estimated. The variables involved are defined as bellow:

$$
\begin{array}{r}
g_{i, A}=E_{i, A} / E_{i} \\
g_{A}=E_{N, A} / E_{N} \\
L Q_{i}^{A}=g_{i}^{A} / g^{A} \\
E\left(g_{i}^{A}\right)=p_{i, A} \\
E\left(g_{A}\right)=p_{A}
\end{array}
$$

Consequently, based on the Tyler series of $L Q_{i}^{A}$, the variance can be approximated as bellow:

$$
\begin{align*}
\operatorname{var}\left(L Q_{i}^{A}\right) & \left.\equiv \operatorname{var}\left(g_{i, A}\right) / g_{A}\right) \approx \frac{\operatorname{var}\left(g_{i, A}\right)}{p_{A}{ }^{2}}+\frac{p_{i, A}^{2} \operatorname{var}\left(g_{A}\right)}{p_{A}{ }^{4}}-\frac{2 p_{i, A} \operatorname{cov}\left(g_{i, A}, g_{A}\right)}{E_{N} \times p_{A}^{3}} \\
& =\frac{p_{i, A}\left(1-p_{i, A}\right)}{E_{i} \times p_{A}^{2}}+\frac{p_{i, A}^{2} \sum_{j=1}^{n} E_{j} p_{j, A}\left(1-p_{j, A}\right)}{E_{N}^{2} \times p_{A}^{4}}-\frac{2 p_{i, A}^{2}\left(1-p_{i, A}\right)}{E_{N} \times p_{A}^{3}} \tag{3.2.2}
\end{align*}
$$

Thereafter, the (1- $\alpha$ ) confidence interval for the $L Q_{r}$ is $g_{r} / g \pm Z_{\alpha / 2} \sqrt{v\left(L Q_{r}\right)}$, and $Z_{\alpha / 2}$ is the $\alpha / 2$ percentile of standard normal distribution.

O'Donoghue and Gleave(2004) contributed the standard location quotient to contain the same issue, with the statistic as bellow:

$$
\begin{gather*}
S L Q_{i r}=\left(L Q_{i r}-\overline{L Q_{i}}\right) / s t d\left(L Q_{i}\right)  \tag{3.2.3}\\
S L L Q_{i r}=\left(\log \left(L Q_{i r}\right)-\overline{\log \left(L Q_{i}\right)}\right) / s t d\left(\log \left(L Q_{i}\right)\right) \tag{3.2.4}
\end{gather*}
$$

If LQ is distributed normally, the SLQ is a z-statistic. Otherwise, the logarithmic of LQ quotient is used to be transformed to SLLQ. In any case, the data must be verified by the normality test.The shortcoming is very
obvious that the not all industries' distribution can be normal.Due to the heterogeneity of different industries, this assumption is strongly challenged. To overcome this, the bootstrap method is used here to contain this issue, as there is no any pre-assumption about the the distribution of SLQ or SLLQ. Especially, the the mean of 95 percentile cut-off value and its estimate standard error are derived here to construct a confidence interval for the 95 percentile cut-off value. Therefore, the subregion with the quotient outnumbering the cut-off value is reasonably to be taken as the industry i agglomeration region.

The enhancements above don't solve the firm size problem which is close to the level of market competition. Holmes and Stevens (2002) introduced a method for decomposition of the LQ to overcome that obstacle. The LQ is decomposed to its components and put together in a new way. Besides the employment number of different industries in different subregions, the count of firms and their employee's count are required. The composition of the LQ is as bellow:

$$
\begin{equation*}
Q_{i r}^{x}=Q_{i, r}^{n} \times Q_{i, r}^{s} \tag{3.2.5}
\end{equation*}
$$

where

$$
\begin{aligned}
& Q_{i r}=L Q_{i r} \\
& Q_{i, r}^{n}=\left(n_{i r} / E_{r}\right) /\left(n_{i} / E_{n}\right) \\
& Q_{i, r}^{s}=\left(E_{i r} / n_{i r}\right) /\left(E_{i} / n_{i}\right)
\end{aligned}
$$

Among the variables here, newly added includes: $Q_{i r}$ denotes the employment location quotient of industry i in subregion $\mathrm{r}, n_{i r}$ denotes the number of industry i's firms in subregion $\mathrm{r}, n_{i}$ denotes the the number of industry i's firms in the total region. Consequently through this process, the LQ quotient is decomposed to two sources: (1) $Q_{i, r}^{n}$ the ratio that the number of industry i's firms per capita divided by the total region's level; (2) $Q_{i, r}^{s}$ the ratio that the average size of industry i's firms divided by the total region's level.Then take the natural logarithm of function 3.2.5 and let the lower case q's represent their counterparts, the function below can be derived:

$$
\begin{equation*}
q_{i r}^{x}=q_{i, r}^{n}+q_{i, r}^{s} \tag{3.2.6}
\end{equation*}
$$

Then they use the $\beta$-coefficients of regressing $q_{i r}^{n}$ on $q_{i r}^{x}$ alongside with those of regressing $q_{i r}^{s}$ on $q_{i r}^{x}$, which are as below:

$$
\begin{align*}
& \beta^{n}=\operatorname{cov}\left(q_{i r}^{x}, q_{i r}^{n}\right) / \operatorname{var}\left(q_{i r}^{x}\right)  \tag{3.2.7}\\
& \beta^{s}=\operatorname{cov}\left(q_{i r}^{x}, q_{i r}^{s}\right) / \operatorname{var}\left(q_{i r}^{x}\right) \tag{3.2.8}
\end{align*}
$$

Due to the function 3.2.6, $\beta^{n}+\beta^{s}=1$. Especially, if ether of these two $\beta^{\prime} s$ equals to zero, then the variance of the stand LQ quotient is totally accounted for by the other component. Moreover, $\beta^{s}$ the relation between the agglomeration and firm's average size gets more attention. Furthermore, other than the average size of firms, a firm level localization is introduced to estimate the effect of subregion's localization quotient $q_{e}^{x} \equiv q_{i r}^{x}$
on a individual firm size , where e refers to firm e as well as industry i and location r of this firm. Accordingly for any firm with size $E_{e}$, the firm level size quotient and the $\beta$-coefficient are defined as bellow:

$$
\begin{gather*}
q_{e}^{s}=\ln \left[E_{e} /\left(E_{i} / n_{i}\right)\right]  \tag{3.2.9}\\
\beta_{e}^{s}=\operatorname{cov}\left(q_{e}^{x}, q_{e}^{s}\right) / \operatorname{var}\left(q_{e}^{x}\right) \tag{3.2.10}
\end{gather*}
$$

Nevertheless, even if the distribution of firm size is independent from the location of industry, under the case that there are just a infinite number of firms,the $\beta_{e}^{s}$ and $\beta^{s}$ is biased due to big-sized firms. In order to contain this issue, a excluded localization quotient $\tilde{Q}_{e}^{x}$ is introduced that current firm is excluded when calculating the standard LQ. Meanwhile, a excluded firm-size level quotient $\tilde{Q}_{e}^{s}$ is defined as well. And the natural logarithm of these two quotients are as bellow:

$$
\begin{gather*}
\tilde{q}_{e}^{x}=\ln \left[\left(\frac{E_{i r}-E_{e}}{E_{r}-E_{e}}\right) /\left(\frac{E_{i}-E_{e}}{E_{n}-E_{e}}\right)\right]  \tag{3.2.11}\\
\tilde{q}_{e}^{s}=\ln \left[E_{e} /\left(\frac{E_{i}-E_{e}}{n_{i}-1}\right)\right] \tag{3.2.12}
\end{gather*}
$$

Therefore, with regressing $\tilde{q}_{e}^{s}$ on $\tilde{q}_{e}^{x}$, the coefficient $\tilde{\beta}_{e}^{s}$ can be utilized to find the correlation between a firm's size with its decision whether to locate a subregion with high LQ value. Moreover just as $q_{i r}^{x}, \tilde{q}_{e}^{x}$ can also be decomposed to two components as below:

$$
\begin{equation*}
\tilde{q}_{e}^{x}=\bar{q}_{e}^{n} \times \bar{q}_{e}^{s} \tag{3.2.13}
\end{equation*}
$$

where

$$
\begin{aligned}
& \bar{q}_{e}^{n}=\ln \left[\left(\frac{n_{i r}-1}{E_{r}-E_{e}}\right) /\left(\frac{n_{i}-1}{E_{n}-E_{e}}\right)\right] \\
& \bar{q}_{e}^{s}=\ln \left[\left(\frac{E_{i r}-E_{e}}{n_{i r}-1}\right) /\left(\frac{E_{i}-E e}{n_{i}-1}\right)\right]
\end{aligned}
$$

Therefore, with regressing $\tilde{q}_{e}^{s}$ on ether of the components above, we can estimate that which component accounts more for the decision making of current firm. For a firm e, it may choose a low LQ valued subregion to gain potential market share or to a high LQ valued subregion to gain the benefit brought out by the agglomeration there, which may be mainly accounted for by a large number of peers there or just a small number of large-scaled firms.

## Continuous-space localization indices

Based on the kernel density estimation and simulation, Gilles Duranton and Henry G. Overman(2004) introduce a new method to estimate the localization on a continuous space. Especially, they make some enhancements over discrete indices that (1) no evenness presumption for each subregion which means that localization
caused by area, population size, natural resources or specific industry characteristics are not accounted for here;(2) Each firm's location is handled independently and not aggregated in some boxes(provinces, cities, counties, etc.),so the Modifiable Area Unit Problem is ruled out ;(3) The overall industrial localization tendency is compromised as the evolution of a industry's overall location pattern can be updated periodically in its calculation process. (4) Without any distribution presumption, Monte Carlo approach is utilized to simulate the pattern of randomness for each industry, therefore the non-randomness(i.e industrial localization) can be measured with the statistical significance of departure. Nevertheless, this is method is very demanding on the geographic information about each firm enrolled.

The first step is to construct kernel estimates of $k$-densities centering on bilateral distance between each pair of n's firms within current industry. Especially, the distance is a proxy for the true approximating time and pecuniary cost between them, so it may be distorted by the distance algorithm used ${ }^{9}$ and the actual traffic conditions such as topography and road density. And the estimator can be listed as bellow:

$$
\begin{equation*}
\hat{K}(d)=\frac{1}{n(n-1)} \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} f\left(\frac{d-d_{i, j}}{h}\right) \tag{3.2.14}
\end{equation*}
$$

$d_{i, j}$ is the distance between firm i and $\mathrm{j}, \mathrm{h}$ is the chosen bandwidth and f is the kernel function. As the distance is absolutely above zero, in order not to underestimate the density around the bounder zero they adopt the reflection method by Silverman (1986).

Secondly, although function (3.2.14) is a U-statics like shaped and firms are presumed to locate independently, the bilateral distance are still dependent.Therefore, they adopt the Monte Carlo simulation to measure the departure from the randomness.

Thirdly, other than re-sampling the original distance calculated from census data, it is simulated that each firm randomly draws the existing sites of the industry they belong to without replacement as one existing location can only hold a firm in reality.Thereafter the bilateral distance can be calculated.

As to the construction of confidence interval, it has local confidence interval and global confidence interval constructed for the $d \in[0, \tilde{d}]$, where $\tilde{d}$ is the median among all the bilateral distances. Local confidence interval is to take the $\alpha$ and 1 - $\alpha$ percentile with ascending the density of the distance d for all the simulations simultaneously. And the lower bound and upper bound are denoted as $\bar{K}(d)]$ and $\underline{K}(d)$. So it is reasonable to use these outcomes as counterfactual to be compared with the real density estimated by the function (3.2.14). Nevertheless, due to the autocorrelation between distances and the smoothing techniques, the agglomeration is correlated with the dispersion which is against the randomness, other than take the percentile on each distance, global confidence interval is to construct the upper and lower bound that only $\alpha$ simulations can hit the upper bounds or lower bound, which are denoted as $\overline{\bar{K}}(d)]$ and $\underset{\underline{K}}{ }(d)]$ in the interval of $[0, \tilde{d}]$. Accordingly for industry i ,the indices of localization is defined as bellow:

For local confidence interval:

[^6]localization index
\[

$$
\begin{equation*}
\gamma(d) \equiv \max (\hat{K}(d)-\bar{K}(d), 0) \tag{3.2.15}
\end{equation*}
$$

\]

as well as dispersion index:

$$
\begin{equation*}
\psi(d) \equiv \max (\underline{K}(d)-\hat{K}(d), 0) \tag{3.2.16}
\end{equation*}
$$

For global confidence interval:
localization index:

$$
\begin{equation*}
\Gamma(d) \equiv \max (\hat{K}(d)-\overline{\bar{K}}(d), 0) \tag{3.2.17}
\end{equation*}
$$

dispersion index:

$$
\Psi(d) \equiv\left\{\begin{align*}
\max (\underline{K}(d)-\hat{K}(d), 0) & \text { if } \sum_{0}^{\tilde{d}} \Gamma(d)=0  \tag{3.2.18}\\
0 & \text { otherwise }
\end{align*}\right.
$$

Where we can notice that if a industry's $\hat{K}(d)$ surpass the upper bound anywhere in the interval $[0, \tilde{d}]$,dispersion is not accounted for with respect to this industry. To contain the employment into the density estimation for industry $i$, the density can be defines as bellow:

$$
\begin{equation*}
\hat{K}_{e m p}(d)=\frac{1}{h \sum_{i=1}^{n-1} \sum_{j=1+1}^{n} e(i) e(j)} \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} e(i) e(j) f\left(\frac{d-d_{i, j}}{h}\right) \tag{3.2.19}
\end{equation*}
$$

where $e(i)$ and $e(j)$ are the numbers of employee owned by firm $i$ and $j$. To sum all the localization and dispersion index respectively across the distance $d$ within the range of $(0-M e d)$, we can get the cross-distance localization and dispersion indices for a given industry sector. And $M e d$ is the median distance among all the establishment. Likely with summing all industries' localization and dispersion indices for a given distance level $d$ in the same the range above, the composite localization and dispersion indices for distance level $d$ can be derived.

### 3.2.1 Test of spatial autocorrelation

Traditional regression models mostly stipulate the assumptions about exogenousity of regressors, scedasticity and serial correlation restriction on the residual part. Whereas the cross-section dependence (abbre. CD) issue is absent in these literatures. Nevertheless our purpose here is just to probe into the cross-section relation(i.e. spatial autocorrelation)as the sections here are cities. The test used to detect cross-section dependence can be categorized into 2 groups:

1. cross-section data for spatial observation

For a priori or a given static spatial structure, Moran' I test is mostly adopted to detect the significance of
spatial autocorrelation.

$$
\begin{align*}
I & =\frac{N}{W} \times \frac{\sum_{i} \sum_{j} w_{i j}\left(x_{i}-\bar{x}\right)\left(x_{j}-\bar{x}\right)}{\sum_{i}\left(x_{i}-\bar{x}\right)^{2}} \\
& =\frac{\sum_{i} \sum_{j} w_{i j} z_{i} z_{j}}{\sum_{i} z_{i}^{2}}=\frac{\sum_{i}\left(z_{i} \times \sum_{j} w_{i j} z_{j}\right)}{\sum_{i} z_{i}^{2}} \tag{3.2.20}
\end{align*}
$$

where W is a row normalized spatial weight matrix, $x_{i}$ is the variable of interest, $\bar{x}$ is the grand mean of $x_{i}$, therefore z means z -score as $z_{i}=\frac{x_{i}-\bar{x}}{S D\left(x_{i}\right)}$. In others words, Moran's I can be taken as a $\beta$ slope estimator of regressing $x_{i}$ on its spatial lag variable as $\sum_{j} w_{i j} z_{j}$.
2.panel data: As Moran' I is quite clumsy with the panel data, Lagrange Multiplier test was utilized to diagnose the CD's significance as bellow (Pesaran 2004):

$$
\begin{array}{r}
C D_{l m}=T \sum_{i=1}^{N-1} \sum_{j=i+1}^{N} \hat{\rho}_{i j}^{2} \\
\hat{\rho}_{i j}=\hat{\rho}_{j i}=\frac{\sum_{i=1}^{T} e_{i t} e_{j t}}{\left(\sum_{i=1}^{T} e_{i t}^{2}\right)^{1 / 2}\left(\sum_{j=1}^{T} e_{j t}^{2}\right)^{1 / 2}} \tag{3.2.21}
\end{array}
$$

where $e_{i t}$ is the estimation of $u_{i}$ by estimating OLS model that $e_{i t}=y_{i t}-\hat{\alpha}_{i}-\hat{\beta}_{i}^{\prime} x_{i t}$ for each i.And based on the regression of $e_{i t}$ on $e_{j t}$ and maximum likelihood estimation, the statistic above can be derived. And under the assumption of cross-section independence,hypothesis $H_{0}$ can listed as $T \hat{\rho}_{i j}^{2} \stackrel{a}{\sim} \chi_{1}^{2}$ with pairwise $\hat{\rho}_{i j}^{2}$ being asymptotically independent as $T \rightarrow \infty$.Therefore the static $C D_{l m}$ in 3.2.21 is asymptotically distributed as chi-squared with $N(N-1) / 2$ degrees of freedom if T is large enough.

Nevertheless statistic $C D_{l m}$ in 3.2.21 is probably in distortion to handle the large N and short T panel data. In our panel data T is just 16 , so in order to accommodate the short panel another more general statistic (Pesaran 2004) is adopted here.

$$
\begin{equation*}
C D_{l m}^{*}=\frac{\sum_{i=1}^{N-1} \sum_{j=i+1}^{N} \sum_{t=1}^{T} \hat{\xi}_{i t} \hat{\xi}_{j t}}{\left\{\sum_{i=1}^{N-1} \sum_{j=i+1}^{N} \sum_{t=1}^{T} \hat{\xi}_{i t}^{2} \hat{\xi}_{j t}^{2}\right\}^{1 / 2}} \tag{3.2.22}
\end{equation*}
$$

Different with 3.2.21, $\hat{\rho}_{i j}$ is calculated with the scaled residual $\xi_{i t}=\frac{e_{i t}}{e_{i t}^{i} e_{i t}}$ as $\hat{\rho}_{j i}=\frac{\sum_{i=1}^{T} e_{i t} e_{j t}}{\left(\sum_{i=1}^{T} e_{i t}^{e}\right)^{1 / 2}\left(\sum_{j=1}^{T} e_{j t}^{2}\right)^{1 / 2}}=$ $\sum_{i=1}^{T} \hat{\xi}_{i t} \hat{\xi}_{j t}$. In this general form unbalanced panel and a priori spacial weight matrix can be accommodated here. Especially the row-normalized neighbour matrix can also be adopted here just as it is, when dependence is only diagnosed among the current site $i$ and its neighbours $j$.
However in order to get the unbiased and consistent result, the following assumptions must be satisfied for the panel data model adopted:
(1)For each ithe disturbance $u_{i t}$ are serially independent with zero means and the variance $\sigma_{i}^{2}$ that $0<\sigma_{i}<\infty$.
(2)Under the null hypothesis that $H_{0}: u_{i t}=\sigma_{i} \epsilon_{i t}$ with $\epsilon_{i t}$ is in an independent and identical distribution $I I D(0,1)$ for all i and t , the distribution of $\epsilon_{i t}$ is symmetrically distributed around 0 .
(3)The regressors $x_{i t}$ are strictly exogenous such that $E\left(u_{i t} \mid X_{i}\right)=0$ for all i and t where $X i=\left(x_{i 1}, x_{i 2}, \ldots, x_{i T}\right)^{\prime}$ and $X i^{\prime} X i$ is a positive definite matrix.
(4)Longitude $T>k+1$ and the OLS residuals $e_{i t}$ are not all zero.

### 3.2.2 Regression models

Moineddin,et al.(2003) assumes that the probability to get engaged in a sector are independent across all the subregions. Obviously, this assumption doesn't hold for the scenario of location choice by firms, as firms used to consider competition, accessibility to upstream and downstream industries, traffic, scale, etc of the available location choices. Here I mainly focus on the way to estimate the correlation between the firm's scale with proxy variables about the factor mentioned in each subregion. In most literatures the dependant variables are only influenced by current subregion's regressors, which neglect the effect by other subregions' variables or residuals.

For observations about cities it's very attractive to detect whether and to what extent, the dependant variables are affected by other subregions. Therefore the regression models here must take the cross-section correlations into consideration.

Firstly FE model(i.e. fixed effect model), RE model(i.e. seemingly unrelated regression with pre-assumed error structure), fixed effect generalised least squares model(FEGLS) and feasible general least squares model (FGLS) are adapted here as the basic model. And it is still very important to stress their resumptions beforehand. These 4 models can be listed in the same structure as bellow:

$$
\begin{equation*}
y_{i}=X_{i} \beta+c_{i} e_{T}+u_{i} \tag{3.2.23}
\end{equation*}
$$

,where $y_{i}$ is a $\mathrm{T} \times 1$ vector, $X_{i}$ is a $\mathrm{T} \times \mathrm{K}$ matrix, $e_{T}$ is a $\mathrm{T} \times 1$ vector of ones, $u_{i}$ is a idiosyncratic error and $c_{i}$ are time-invariant variables which are taken as parameters in FE and FEGLS models, but exogenous stochastic variable in RE and FGLS models. In addition the assumptions is summed up as bellow:

1. FE model
(1) $E\left(\ddot{u}_{i t} \mid x_{i}\right)=E\left(u_{i t} \mid x_{i}\right)-E\left(\bar{u}_{i t} \mid x_{i}\right)=0$,
(2) $\operatorname{rank}\left(\sum_{t=1}^{T} E\left(\ddot{x}_{i t}^{\prime} \ddot{x}_{i t}\right)\right)=\operatorname{rank}\left(E\left(\ddot{X}_{i}^{\prime} \ddot{X}_{i}\right)\right)=K$,
(3) $E\left(u_{i} u_{i}^{\prime} \mid x_{i}, c_{i}\right)=\sigma_{u}^{2} I_{t}$;

## 2. FEGLS model

With the existence of the heteroskedasticity and serial correlation, the third pre-assumption of fixed effect model is relaxed as $E\left(u_{i} u_{i}^{\prime} \mid x_{i}, c_{i}\right)=\Lambda$, a $T \times T$ positive definite matrix, which can be Cholesky decomposed.Although the specific distribution of $u_{i t}$ and the serial correlation are agnostic, the estimator of $\beta$ can still be consistent and unbiased. Accordingly the second assumption of FE model is updated as $\operatorname{rank}\left(E\left(\ddot{X}_{i}^{\prime} \Omega^{-1} \ddot{X}_{i}\right)\right)=K$, where $\Omega=Q^{T} \Lambda Q$ and $Q^{T}$ is a demeaning process to get rid of time-invariant individual effect $c_{i}$;
3. RE model
(1) $E\left(u_{i t} \mid x_{i}, c_{i}\right)=0$,
(2) ${ }^{10} E\left(c_{i} \mid x_{i}\right)=E\left(c_{i}\right)=0$,
(3) $\operatorname{rank} E\left(X_{i}^{\prime} \Omega^{-1} X_{i}\right)=\mathrm{K}$,
(4) $E\left(u_{i} u_{i}^{\prime} \mid x_{i}, c_{i}\right)=\sigma_{u}^{2} I_{T}$,
(5) $E\left(c_{i}^{2} \mid x_{i}\right)=\sigma_{c}^{2}$. So for each object i, its idiosyncratic errors $E\left(v_{i}\right)=E\left(c_{i}\right)+E\left(u_{i}\right)$ have a special homogeneous form as:

$$
\Omega=E\left(v_{i} v_{i}^{\prime}\right)==\left[\begin{array}{cccc}
\sigma_{c}^{2}+\sigma_{u}^{2} & \sigma_{c}^{2} & \ldots & \sigma_{c}^{2} \\
\vdots & \ddots & \ddots & \\
\vdots & & \ddots & \sigma_{c}^{2} \\
\sigma_{c}^{2} & \ldots & \ldots & \sigma_{c}^{2}+\sigma_{u}^{2}
\end{array}\right]
$$

## 4. FGLS model

Just as the relaxation of idiosyncratic error's assumption, $\Omega=E\left(v_{i} v_{i}^{\prime}\right)$ which can be estimated with the residuals of pooled OLS residuals. And only if the exogenousity assumption in RE effect is not violated, FGLS's estimator is consistent unbiased and more efficient than FEGLS model.

With the existence of cross-sector dependence, the basic regression models can be extended to spatial models in order to contain it. Manski (1993) points out that three different types of interaction effects can explain why an observation associated with a specific location can be dependent on observations at other locations: (i) endogenous interaction effects, where the decision of a spatial unit (or its economic decision makers) to behave in some way depends on the decision taken by other spatial units; (ii) exogenous interaction effects, where the decision of a spatial unit to behave in some way depends on independent explanatory variables of the decision taken by other spatial units - if the number of independent explanatory variables in a linear regression model is $K$, then the number of exogenous interaction effects is also $K$, provided that the intercept is considered as a separate variable; and (iii) correlated effects, where similar unobserved environmental characteristics result in similar behaviour. Therefore A general nesting spatial(i.e. Manski model) model for N sections with a time span of T can be listed as bellow:

$$
\begin{array}{r}
Y=\rho W Y+\alpha \iota_{N}+X \beta+W X \theta+\mu  \tag{3.2.24}\\
\mu=\lambda W \mu+\epsilon
\end{array}
$$

Where $Y$ denotes an $N \times 1$ vector consisting of one observation on the dependent variable for every unit in the sample $(i=1, \ldots, N), \iota_{N}$ is an $N \times 1$ vector of ones associated with the constant term parameter $\alpha, W$ denotes an $N \times N$ spatial weights matrix, X denotes an $N \times K$ matrix of exogenous explanatory variables with the associated parameters $\beta$ contained in a $K \times 1$ vector, the variable $W Y$ denotes the endogenous interaction effects among the dependent variables, $W X$ the exogenous interaction effects among the independent vari-

[^7]ables, and $W \mu$ the interaction effects among the disturbance terms of the different spatial units. $\rho$ is called the spatial autoregressive coefficient, $\lambda$ the spatial autocorrelation coefficient, while $\theta$ as for $\beta$, represents a $K \times 1$ vector of fixed but unknown parameters.

It seems very reasonable to adopt this general model, but J.Paul Elhorst(2010) proved that although the 3 types of interaction can be estimated technically the endogenous and exogenous effects can not be distinguished from each other. Therefore the main spatial panel models adopted here include two categories which impose restrictions on the interaction parameters $\rho, \theta$ respectively, alongside with existence of $\lambda$. The reason is that significant cross section dependence exists with basic model's regression results.

1. SAC(spatial autoregressive combined model)

$$
\begin{array}{r}
y=X \beta+\alpha \iota_{N T}+\rho\left(I_{T} \bigotimes W\right) y+u=Z \gamma+u \\
Z=\left(X, \iota_{N},\left(I_{T} \bigotimes W\right) y\right), \gamma^{\prime}=\left(\beta^{\prime}, \alpha, \rho\right)  \tag{3.2.25}\\
u=\left(\left(I_{T} \bigotimes \lambda W\right) u+\epsilon\right. \\
\epsilon=\left(e_{T} \bigotimes I_{N}\right) \mu+v
\end{array}
$$

2. SDEM(Spatial Durbin error model)

$$
\begin{array}{r}
y=X \beta+\left(I_{T} \bigotimes W\right) X \theta+u=Z \gamma+u \\
Z=\left(X,\left(I_{T} \bigotimes W\right) X\right), \gamma^{\prime}=\left(\beta^{\prime}, \theta^{\prime}\right)  \tag{3.2.26}\\
u=\left(\left(I_{T} \bigotimes \rho_{2} W\right) u+\epsilon\right. \\
\epsilon=\left(e_{T} \bigotimes I_{N}\right) \mu+v
\end{array}
$$

$E(\epsilon)=\mu$ and $\operatorname{var}(\epsilon)=v^{2}$ in these 2 models with $X$ as a $N T \times k$ matrix for T times' observation about k variables of interest, $\iota_{N T}$ is a $N \times T$ vector of ones.

Based a spatial lag two stage least squares estimator(weighted 2 stages least squares for the fixed effect here) by H.Kelejian (2004) on the these two models the spillover effect can be inferred by the direct effects and indirect effects. For SAC model,they can be derived as bellow(chapter2 Lasage, 2008):

$$
\begin{array}{r}
\left(I_{N T}-\rho\left(I_{T} \bigotimes W\right)\right) y=X \beta+\alpha \iota_{N T}+u \\
y_{t}=\sum_{r=1}^{k} S_{r}(W) x_{r t}+V(W) \iota_{n} \alpha+V(W) u_{t}  \tag{3.2.27}\\
S_{r}=V(W) I_{N} \beta_{r} \\
V(W)=\left(I_{N}-\rho W\right)^{-1}=I_{N}+\rho W+\rho^{2} W^{2}+\rho^{3} W^{3}+\ldots
\end{array}
$$

,where $y_{t}$ is $1 \times N$ vector of $t$ th time observation. $x_{r t}$ is $1 \times N$ vector of $t$ th time's observation about $r$ th variable of interest. And the measured impacts is defined as bellow:

$$
\begin{array}{r}
\bar{M}(r)_{\text {direct }}=n^{-1} \operatorname{tr}\left(S_{r}(W)\right) \\
\bar{M}(r)_{\text {total }}=n^{-1} \iota_{N}^{\prime} S_{r}(W) \iota_{N}  \tag{3.2.28}\\
\bar{M}(r)_{\text {indirect }}=\bar{M}(r)_{\text {total }}-\bar{M}(r)_{\text {direct }}
\end{array}
$$

Moreover the direct effect $\bar{M}(r)_{\text {direct }}$ not only include the immediate direct effect ( $I_{N}$ in $V(W)$ ) but also the feedback effect by its neighbours.(diagonals of $\rho W+\rho^{2} W^{2}+\rho^{3} W^{3}+\ldots$ ). The off-diagonals' sum measures the indirect effects which numerically equals to emanating effects ${ }^{111}$ (Hondroyiannis et al. 2009) or vulnerability effects, which is the row's sum $\sqrt{11}$ As to the SDEM model, direct impacts and indirect impacts are explicitly measured by $\beta$ and $\theta$ respectively.

### 3.3 Data and variables

### 3.3.1 Data

Yearly localization quotient of function 3.2 .5 will be applied to the ASIE database using the subtotal employee number. Without using the arbitrary threshold value of one,the confidential interval can be calculated based on the method of Moineddin(2003).

To be compared with the discrete agglomeration indices, employee weighted global localization and dispersion indices based on $K(d)$ function is calculated. And it can be inferred about the difference between the outcomes of these two categories' indices.Especially all the geographic information is scraped from the google map API $]^{13}$ based on the zip codes attached to ASIE.

According to the zip code composing rules by Chinese post system, the first 2 digits represent the provincial administration division, the 3rd and 4th digits represent the prefectural-level and county-level administration division, and the last 2 digits represent the delivery office. Therefore it is achievable to scrap the delivery offices' geographic information. To calculate the mutual distance, all the scraped latitudes and longitudes are projected to euclidean space with coordinates reference system set as WGS84.

As to the specific zip codes' data process in ASIE, inaccurate entry is a serious matter that some zip codes are contaminated by abnormally excessive entries with last 2 digits as zeros. Indiscreetness with these raw data can cause serious biasness. To moderate this biasnees interpolation is utilized by replacing the erroneous data entries with time serially nearest zip code entries. Furthermore each firm can only hold a unique position in kernel distance function according to Duranton and Overman (2004), therefore each firm's coordinate are estimated by jitterring the delivery offices' coordinates. In addition jitter deviates are less than the half of minimum distance among all zip codes' coordinates. This ad hoc method probably generates a systematic

[^8]error but can simplify the computation process significantly．
To get free from any distribution presumption，I try to resort to other robust methods to estimate the discrete location measurement as well as the scale measurement．The most intuitive way is to adopt the kernel density estimation，but the ASIE data is exhaustive with regards to cities and the pre－decided scope＇s firms．So the distribution of LQ or SLQ can only be the forms of probability mass distribution．Moreover according to the function form of LQ values，each subregion＇s LQ is correlated through the denominator for the given industry． And it can cause systematic errors to bootstrap the LQ or SLQ values directly．Therefore I am restrained from estimating the robust statistics about the LQ values．In ASIE a 4 digits industry classification is provided for the level－1 categories of mining，manufacture and public services．We only focus on the manufacture sector as the other two are more vulnerable to the unevenness attributes of each city．As to the manufacture sector，we mainly focus on the 2 digit classification．In addition，NBS have amended the industry classification standards twice during year 1998－2013 $\sqrt{14}$ ，which is divided into 3 stages．To unify the classification，I transfer all the indus－ try codes uniformly to the GB／T $4754-2002^{15}$ according to the cross－reference tables by NBS $\sqrt{16}$ With respect to the scope of cities here，it refers to $332{ }^{17}$ prefectural－level units， 4 provincial－level cites and 8 other spatial units 18

[^9]
## Main cities in Chinese mainland

Figure 3.1: Main cities in Chinese mainland

### 3.3.2 Variables

For any given industry A,linear models for N's subregions and T's periods can be listed as bellow:

$$
\begin{equation*}
q_{i, A}^{s}=F\left(q_{i r}^{x}, \text { competition }_{i, t}^{A}, \text { diversification }_{i, t}^{A}\right) \tag{3.3.1}
\end{equation*}
$$

, where $q_{i, A}^{s}$ and $q_{i r}^{x}$ are defined as function 3.2.6; competition $_{i, t}^{A}$ and diversification $n_{i, t}^{A}$ are measurements about the competition and the diversification for current industry A in subregion i. And both of these are expended based on the Herfindal index. The index to measure competition is as bellow:

$$
\begin{gather*}
\text { competition }_{i, t}^{A}=\ln \left(\frac{1}{H H I_{i, t}^{A}}\right)  \tag{3.3.2}\\
H H I_{i, t}^{A}=\sum_{f \in S_{i, t}^{f, A}}\left(\frac{E_{f, t}}{E_{i, t}^{A}}\right)^{2}
\end{gather*}
$$

,where $S_{i, t}^{f}$ means all the firms that belong to the subregion i' firm group of current industry, $E_{f, t}$ means firm $\mathrm{f}^{\prime} \mathrm{s}$ number of employees in period t , and $E_{i, t}^{A}$ means subregion i's number of A industry's employees in period t .

Likely another excluded competition index can be achieved to measure the competition level of current firm $f$ :

$$
\begin{gather*}
\text { competition }_{i, t}^{f, A}=\ln \left(\frac{1}{H H I_{i, t}^{f, A}}\right)  \tag{3.3.3}\\
H H I_{i, t}^{A, f}=\sum_{j \in S_{i, t}^{f, A}}\left(\frac{E_{j, t}}{E_{i, t}^{A}}\right)^{2}
\end{gather*}
$$

The other index to measure industry diversification is as bellow:

$$
\begin{align*}
& \text { diversification } i_{i, t}^{A}=\ln \left(\frac{1}{H_{i, t}}\right)  \tag{3.3.4}\\
& H I_{i, t}^{A}=\sum_{\bar{a} \in \bar{A}}\left(\frac{E_{\bar{a}, t}^{j}}{E_{i, t}-E_{i, t}^{A}}\right)^{2}
\end{align*}
$$

,where $\bar{A}$ means all the manufacture sectors other than A that belong to the subregion i, $E_{\bar{a}, t}^{j}$ means the count of $\bar{a}$ sector's employees in period t and subregion i , and $E_{i, t}^{A}$ means subregion i's count of A industry's employees in period t . To contain the spatial autocorrelation factor, based on the models mentioned above a spatial weight matrix is added in, which is constructed on the neighbouring relation among the cities in China. Through this, it is aimed to detect the spillover effect which includes emanating effect and vulnerability among the cities.Especially emanating effect means how much the current city's one unit change will affect all the other cites and vulnerability effect means how a city reacts to a uniform worsening(decrease) in all other cities.

Besides competition $n_{i, t}^{A}$ and diversification $n_{i, t}^{A}$, other control variables are introduced as bellow:
City_ind_E: each sector's yearly total number of employees in city i.For missing entries of data, interpolation is adopted here.
City_E:yearly total of manufacture sectors' employees in city i.
CusumYr_pat:one year lagged cumulative number of invent patents in city i , which is based on the data from CNKI.

### 3.4 Results

### 3.4.1 Result of the agglomeration

Firstly,with the function 3.2.1,3.2.3 and 3.2.4 LQ, SLQ and SLLQ values for each city across year 1998-2013 can be calculated. According to the derivation by Moineddin,et al(2003) there is a dichotomy about whether
$p_{i, A}=p_{A}$ across the whole nation. Nevertheless, the normal distribution test about $\frac{E_{i} \times p_{i, A}-E_{i} \times p_{A}}{E_{i} \times p_{A} \times\left(1-p_{A}\right)}$ is denied for all the industries. Therefore only function 3.2 .2 for heterogeneity can be adopted for ASIE. Thereafter based on each city's confidence interval for all industries during the period span,those cities with confidence interval over or bellow one is taken as statistical significantly cites with concentration or dispersion for focal industry. The result can be summed up as figure 7.39 shows. In addition shapiro-wilk test is adopted to test the normality of LQ,SLQ and SLLQ for each sector yearly. And nether LQ, SLO nor SLLQ are in normal distribution. Therefore we cannot directly take the $\alpha$ or 1- $\alpha$ percentile as the cut-off values. According to the results of the yearly shifts(Figure 7.39), thirty 2-digit manufacture sectors can be categorized into 4 groups: Sectors in fields of food and drink manufacturing $(13,14,15)$, apparel $\&$ footwear $(18)$, chemical raw material

Table 3.1

| Group | Characristics | Sector |
| :--- | :--- | :--- |
| Concentration | Count of concentration cities mount up |  |
| Enhanced | and count of dispersion cities level off or drop <br> down | $13,14,15,18$, <br> $26,27,31,32$ |
| Dispersion <br> Enhanced | Count of dispersion cities mount up and <br> count of concentration cities level off or drop <br> down | $17,20,21$, <br> $24,28,40$ |
| Homogeneity <br> Enhanced | Both counts of dispersion and <br> concentration drop down | $16,23,37$ <br> Polorization <br> Enhanced Both counts of dispersion and |
| concentration mount up | 25,43 |  |
| Others | Without significant change | $19,22,29,30,33,34$, |
|  |  | $35,36,39,41,42$ |

\& pharmaceutical(26 27), non-metallic(31), ferrous metals' process(32), petroleum (25) and waste processing(43),more employees are concentrated in limited cities. In addition out of the 344 cities, the sum of concentration and dispersion cities outnumber the count of randomly distributed cites for nearly all the sectors except sector 16(tobacco). however it should still be emphasized that the presumption is far away from reality especially that the geographic unevenness and spatial correlation is not excluded here.

To test the spatial correlation hypothesis, the geographic layout of LQ values for year 1998 and 2013 are depicted as figure in section 7.2. From the figures' result, it seems that high LQ valued cities are more inclined to neighbour each other. To clarify the spatial autocorrelation, Moran' I test is be carried out for each year-sector separately, whereas the longitudinal correlation is not involved here as Moran's I test is not appropriate for the panel data. As to the spatial weights matrix W, a queen-type neighbour based on the Chinese administrative map is generated. If city i and j are neighbours, $W_{i, j}$ is valued as one. Otherwise, it is valued as zero.Secondly each row is normalized as $\frac{W_{i, j}}{\sum_{j} W_{i, j}}$, so sum of each row equals one. As to the cities that have no employee enrolled in the ASIE, their LQ values are all set as zeros.

In table 7.2 year 1998, 2006 and 2013's data are sliced to give a glimpse about the Moran's I two-sided test. Except the bold font figure all the p-values is extremely significant against the hypothesis that firms are randomly distributed. And among these sectors 18, 24, 40 are of with most significance.

Compared with the LQ's result, only sectors of furniture, ferrous medal processing and electrical machinery(21,28 and 39) exhibit obviously strengthening trends of concentration, according to the global localization index in figure 7.37 and 7.38 ,which are based on the result of function 3.2.1919 Especially based on the longitudinal shift with respect to global kernel density result(section 7.4), sectors of food \& agricultural product(13, $14)$, beverage(15), paper \& printing(22, 23), chemical raw material \& pharmaceutical( 26,27 ), non-metallic product, medal processing $(31,32,33)$, and transport equipment $(3720$ hold comparatively stable pattern that: within about 500 kilometres of diameter same sector firms are distributed scarcely, but there are multi clusters keeping over 1000 kilometres away from each other; sectors of tobacco(16) are of random distribution; in sectors related to apparel and footwear $(17,18,19)$ firms keep a stable distribution with one cluster; in sector of timber wood product(20) multi clusters nationally get more adjacent resulting in one cluster; in sector petroleum(25) and rubber product(29) multi clusters emerged nationally; in plastic and artwork sectors $(30,42)$ one cluster evolved into multi clusters; in non-metallic mineral product sector (31) firms keep excessive distances away from their peers with the multi clusters distancing away further; in ferrous metal processing(32) dispersion within 500 kilometres dissolved but without significant agglomeration; in non-ferrous metal processing sector(33) multi national clusters shorten the distances among them, meanwhile firms get concentrated within each cluster; in sectors of education \& art product, chemical fibers and metal products( 24,28 , 34 ) firms get more concentrated into one cluster; in general purpose machinery sector(35) there was one stable cluster; in furniture \& special purpose machinery sectors $(21,36)$ firms get more adjacent to their peers within 500 kilometres with multi clusters emerging with distances of range 800-1000 kilometres; firms of electrical machinery and communication equipment $(39,40)$ were densely distributed within 500 kilometres with multi clusters keeping 1000-1500 kilometres away form each other; firms of measuring instruments sector (41) had a pattern like sector 39 and 40 except late stage during which the multi clusters were integrated as one. At last in sector of waste processing(43), the pattern is very unstable partly because NBS just enlisted this sector from 2002.

### 3.4.2 Result of the basic regressions

Based on the Hausman tests in table 7.32 and 7.33 , RE and FGLS models are not consistent. Meanwhile there are also strong serial correlation and cross section correlation with respect to the residuals of the regression for each sector. Therefore FE and FEGLS models' outcomes are consist compared with the other 3 models,

[^10]and FEGLS is robust to intra-group heterogeneity and serial correlation.
To sum the results, the scale of focal sector $q_{i r}^{x}$ (i.e. $L Q_{\_}$general) are positively correlated with comparative average firm size high $q_{i r}^{s}$ significantly in all sectors and the degree of competition are all significantly negative related with the $q_{i r}^{s}$. Meanwhile diversity of manufacture sector have significantly negative effect except sector 16(tobacco product) and 43 (recycling and disposal of wastes). As for the effect of focal sector's absolute scale(City_ind_E), it is found that swelling sector's size will uniformly contribute to increasing firm's size. Therefore large scale firms of all sectors significantly prefer to be localized in the sites with high Marshallian externalities based on the positive correlation with $L O \_$general and City_ind_E. On the contrary small sized firms are more attracted by Jacobian across sector diversification externalities except tobacco producers and waste processors. Moreover for the traditional sectors like tobacco, apparel, leather, timber, plastic , metal products and waste processing, large sized producers have the significant propensity to distance away from cities with large scaled composite manufacture sector $\left(C_{i t y}=E\right)$. The only exception is with electrical machinery and equipment sector (39) that large sized firms also tend to distance form large cities. As to the competitiveness, it is compliant with the traditional economic theory that with the existence of high competitiveness firms tend to have little influence on the market, which is manifested by the comparative small size of firms.

In addition, the effect of city's cumulative patent count have diverging effects that firm's size is affected positively in sector $17,20,22,25,26,28,29,31,33,35,36$ and 42 . Coreference with the industry classification, in the sector of textile, timber, paper, petroleum, chemical raw material, chemical fiber, rubber, non-metallic mineral product, non ferrous metals, machinery and artworks, other than generating more firms the existing firms tend to grow bigger. For the other sectors the growing patents contribute to more small sized firms participating into the focal sector.

### 3.4.3 Result of the spatial econometric regressions

According to tables in section 7.2, the cross-section dependence is overwhelming across all sectors. To better explain the spatial spillover mechanism among the cities, a KNN(kernel nearest neighbour ) spatial matrix is introduced taking the longest distance between each city' geometry centre with its nearest neighbour's as the threshold value.Thereafter all the cities with geometry centre within the threshold value's distance for focal city are taken as its neighbours. And the the weight is taken as inverse value of the distance between it and its neighbours. Thereafter this spatial weight are row standardized. Other than queen type the reasons to adopt KNN-matrix is that not all cites hold all sectors and there are many isolated cities whose bordering cities hold no firms for focal sector.

Table 7.37, 7.38, 7.42 and 7.43 in section 7.3 sum the basic results from SAC models and spatial Durbin error
models. ${ }^{21}$ Especially based on the regression results of SAC model, the direct and indirect impact result are derived in Table 7.40 and 7.41 according to function 3.2.28 where the significance is inferred based on 200 simulations with the fitted models $\sqrt{22}$. Different from the basic model spatial econometrics models explicitly separate direct effect from the indirect effect for the variable of interest.

With both of the spatial econometric models consistent with basic models, localization quotients contributes to increasing size of firms except sector 24(education, art and sports products). Comparing the results of the two spatial econometric models, the positive indirect effects of localization exist dominantly in sectors of machinery ( 35 \& 36), metal products(34), non-ferrous metal processing(sector 33), plastic(30), non-metallic mineral products(31), petroleum(25), beverage \& alcohol (15) and tobacco(16).For the remained sectors it is not deterministic with the indirect effects of localization.

Meanwhile focal sector's absolute size have deterministic positive indirect effect on neighbouring cities' firm size in petroleum (40), chemical materials(26), non-metallic mineral products(31), metal materials(34), special purpose machinery(36), tobacco(16), measuring instrument(41), artwork(42) and waste processing(43).

Consistently with the basic models Jacobian across sector diversification externalities also have negative direct affects on focal sector firms' size dominantly except sectors of tobacco, leather \& fur and waste processing (16, 19,43 ). As to the indirect effect, negative indirect effects can be ascertained in sectors of petroleum (25), chemical materials(sector 26), non-metallic mineral(sector 31), metals smelting \& processing(sector 31,32) and general purpose machinery(35). With respect to the intra sector diversity or competition, the negative direct effect is consistent with the basic models. Although the indirect effect can be found in both models, the only deterministically negative effect exists in transport equipment sector and the deterministically positive effect exist in measuring instruments and artwork sectors(sector 41 and 42).

Different with the basic models, no negative direct effect of composite manufacture sector can be ascertained. Meanwhile positive direct effect can be found in most sectors except the traditional sectors mentioned for basic models alongside with sectors of electrical machinery and equipment sector(39), food and processing of agricultural products.

As to effects of patents' stock, based on both models it have positive direct effects on petroleum sector's firm size and negative direct effects on sectors of plastic product, smelting and processing ferrous metals, transport equipment and measuring equipment. With respect to the indirect effect, it has ascertained positive positive indirect effects in sectors of textile mills, chemical raw materials, non-metallic mineral products and measuring equipments.

The mentioned findings are all based on the double confirmed results by both SAC and SDEM models. For the other results, they should be compared based on the goodness of fit.Nevertheless there are still no decisive non-nested tests for the SAC panel and SDEM models.

[^11]
## Chapter 4

## Influence of R \& D network on firms' activity

### 4.1 Introduction

Cohen and Levinthal (1990) argue the ability of a firm to recognize the value of new, external information, assimilate it and apply it to commercial ends is critical to its innovation capabilities. Although they concluded that firms are sensitive to the learning environment and absorptive capability is in firm's decision calculus, it is intangible .

Gautam Ahuja(2000) elaborates a theoretical framework-direct ties, indirect ties and structural holes to assess the effect of a firm's network on innovations, which generate a frameworks to probe into absorptive capability. Especially they find increasing structural holes is associated with the reduced innovation output(i.e. granted patents).

Sherzod Aktamov and Yan Zhao(2014) attempt to find the relationship between network centrality indices and innovation performance with the evidence form Chinese auto-mobile industry. The network they constructed are based on the strategic alliance relation centering on the targeted auto-mobile firms. And they found well connection (eigenvector centrality) and direct influence(degree centrality) have a significant and positive effect on innovation(i.e. number of granted patents).

Jinging Zeng, et al (2019) examines the agglomeration effects of industry cluster on firm's innovation performance through the network embeddedness of pharmaceutical companies in Wuhan. The network constructed is measured by inter-enterprise contracts or agreements. And they concluded that betweenness centrality and clustering coefficient have statistically significant and positive effects on enterprise's ability for technological innovation, while the influence from the constraint of structural holes is negative (i.e. maintaining more
structural holes is preferable).

With respect to the agglomeration's effect on firms' innovation performance(launching new product), Zhang(2015) finds that diversity externalities are preferred to localization externalities. To complement the explanation,total factor productivity by Levinsohn and Petrin(2003) is firstly calculated for the enterprises in ASIE.

The existing research about Chinese innovation network mainly focus on the industry-specific regional networks. And the proxy data for the collaboration relation used is limited in comparative closed environment, which is very difficult to be ascertained for foreign researchers. Different from the existing research, it is targeted to probe into the effect of the overall co-patenting network on the firm-level performance alongside with the agglomeration. Co-patenting network can be taken as a token of the R\& D network, tangibilizing mutual relationships among organization. Especially besides the new product output and wage-benefit, it is initiated to diagnose the firm-level estimated production efficiency's relation with co-patenting network, citation network and agglomeration.

### 4.2 Literature

A network is a set of objects (called nodes or vertices )that are connected integratedly. The connections between the nodes are called edges or links. With respect to direction of edge network can be categorized into directed network and undirected network. Without considering the number of edges between two nodes the network is labelled as unweighed network otherwise weighed network. For example figure 4.1 is a weighted undirected network and figure 4.2 is a unweighed directed network. In figure 4.1, the thickness of the edges represent the weights (i.e number) of edges between the connected two nodes. In figure 4.2, the edge stem from one node to another one, but not vice versa necessarily.

### 4.2.1 Network related statistics

## Statistics related to co-patenting network

Degree of node $v$ is the number of edges incident on it in the undirected network.For directed graphs the indegree of a node is the number of edges leading into that node and its outdegree is the number of edges

Figure 4.1: Co-patenting Network centering on ChineseFigure 4.2: Citation Network centering on Chinese firms by firms by 1985 1990
leading away from it to its neighbours(i.e. alters)
Betweenness Centrality of node $v: C_{b}(v)$ is defined as bellow:

$$
\begin{equation*}
C_{b}(v)=\sum_{s \neq t \neq v} \frac{\theta(s, t \mid v)}{\theta(s, t)} \tag{4.2.1}
\end{equation*}
$$

,where $\theta(s, t \mid v)$ means the number of paths between $s$ and $t$ that pass through node $v$ among the shortest paths (i.e. geodesics) between $s$ and $t$, whose count is labelled as $\theta(s, t)$. Betweenness centrality is a indicator of a node's capacity to connect different network subregions.

Burt' s constraint measure $C o(v)$ is defined as bellow:

$$
\begin{equation*}
C_{o}(v)=\sum_{s \in V_{v}, s \neq v}\left(p_{v s}+\sum_{t \in V_{v}, t \neq v, s} p_{v t} p_{t s}\right)^{2} \tag{4.2.2}
\end{equation*}
$$

$V_{v}$ is the set of nodes other than $v$ in $v$ 's ego network, which means that $V_{v}$ are all directly connected to the ego $v$. Consequently $C_{o}(v)$ is low when $v$ is bridging various types of groups in the network. And $p_{v s}=1 / N_{v}$ is the relative link strength between nodes $v$ and $s, N_{v}$ is the degree centrality or number of link incidents upon node $v$. Moreover in weighted network $p_{v s}=N_{v, s} / N_{v}^{w}$, where $N_{v, s}$ is total number of link incidents between $v$ and $s$ and $N_{v}^{w}$ is the number of total link incidents upon node $v$. So Burt's constraint index is used to measure $v$ 's connecting capacity in the neighbourhood region.

The higher Burt's constraint is, the more abundant (i.e. mutually stronger related) the contact is. Burt's constraint is calculated for each ego network of $v$ respectively. To substantiate this algorithm, a simple example is as the following graphs shows.
The numeric attached to the edge means the weights. As both of the graphs are ego network, it means there

Figure 4.3: Ego Network of nodes A, B, C and D
are no other nodes connected to any of these four nodes. In the left network, B, C and D cannot share information except through node $A$. Nevertheless in the right one, $B$ and $C$ can share information directly without through node A who eclipses as the information bridge. Especially in the left one node A monopolize the information among them, in the right one the monopoly is break down between $\mathrm{A}, \mathrm{B}$ and C . Burt's constraint is quite sensitive to probe into this difference. The node A's constraint on left equals $0.25^{2}+0.25^{2}+0.5^{2}=0.375$, compared with $(0.25+0.25 \times 0.5)^{2}+(0.25+0.25 \times 0.5)^{2}+0.5^{2}=0.53125$ on the right one.

## Citation network related statistics

Besides the statistics in 4.2.1, Hyperlink-Induced Topic Search(HITS) algorithms are adopted, which is originally developed by Jon M. Kleinberg(1999)to rate the web page's information during the forming process of internet. Especially to analyse the information source, each page can be estimated by the number of linking to other pages (hub) and the number of being linked by other pages (authority). This algorithm can also be applied to social network analysis with pages taken as nodes. In detail to calculate the hub and authority weights, firstly each node are assigned initial values as $1 / \sqrt{N} 23$ for both the hub weight $h_{i}^{0}$ and authority weight $a_{i}^{0}$. From here on, all nodes $\{i\}$ embraced in the network will be given a updated authority weight $\left\{a_{i}^{t}\right\}$ and a updated hub weight $\left\{h_{i}^{t}\right\}$, which equal the sum of $h_{i}^{t-1}$ of all nodes that points to $i$, and the sum of $\left\{a_{i}^{t-1}\right\}$ of all nodes that is pointed to by i respectively, where the superscript $t$ mean the $t$ th iteration. And this iteration will be carried out that both values converge.

To substantiate this algorithm let square matrix M be the adjacency matrix of a network with N nodes, where all diagonal entries of M are all zeros, element $a_{i j}$ with entry of one or zero means whether there are links from node ito node $j$ or not, and $a_{i j} \neq a_{j i}$ for all as links are directed. In addition vector $v$ and $u$ are authority weight vector and hub weight vector for nodes set $\{i\}$.

[^12]\[

A=\left[$$
\begin{array}{cccc}
0 & a_{12} & \ldots & a_{1 N} \\
\vdots & \ddots & \ddots & \\
\vdots & & \ddots & \ddots \\
a_{N 1} & \ldots & \ldots & 0
\end{array}
$$\right], v=\left[$$
\begin{array}{c}
a_{1} \\
a_{2} \\
\vdots \\
a_{N}
\end{array}
$$\right], u=\left[$$
\begin{array}{c}
h_{1} \\
h_{2} \\
\vdots \\
h_{N}
\end{array}
$$\right]
\]

The initial hub and authority weights for $\{i\}$ is assigned values as $u_{0}^{t}=v_{0}^{t}=[1 / \sqrt{N}, 1 / \sqrt{N}, \ldots 1 / \sqrt{N}]$ and iteration can be summed as:

$$
\begin{array}{r}
\forall i: \text { Authority }: a_{i}^{t+1}=\sum_{j \rightarrow i} h_{j}^{t} \\
\forall i: H u b: h_{i}^{t+1}=\sum_{i \rightarrow j} a_{j}^{t}  \tag{4.2.3}\\
\forall i: \text { Normalize } \sum_{i}\left(a_{i}^{t+1}\right)^{2}=1, \sum_{i}\left(h_{j}^{t+1}\right)^{2}=1
\end{array}
$$

Therefore it can be inferred that:

$$
\begin{array}{rl}
u=A \cdot v & v=A^{T} \cdot u \\
u^{t}=\left(A \cdot A^{T}\right) \cdot u^{t-1} & v^{t}=\left(A^{t} \cdot A\right) \cdot v^{t-1} \tag{4.2.4}
\end{array}
$$

Therefore the converged values of $v$ and $u$ are the eigenvectors of $A A^{T}$ and $A^{T} \cdot A$ respectively.

## Visualization and descriptive statistics about the networks

The Gelphi is utilized here to visualize the yearly edge lists parsed out, some years of which are shown by section 8.2 and 8.3. The overall descriptive statistics can be summed as bellow ${ }^{24}$ Both of the networks extended overwhelmingly from 1998 to 2013, especially after year 2008. Meanwhile the two networks became more sparse that density of both networks decline significantly ${ }^{[25}$

And top 10 organizations ranked with betweenness centrality and HITS yearly for co-patenting and citation networks are in table 8.1, 8.3 and 8.4. It can be found that the universities hold the central position in the co-patenting network alongside with some mega firms in oil, steel, electricity supply and electronic equipment sector. In contrast with co-patenting network, firms hold the dominant positions in citation work. Especially Chinese firms mostly absorb unilaterally for foreign firms, even though the trend slightly reversed in the late stage of the period. In addition there is a shift of industrial composition in the citation network that firms in semiconductor and electronic equipment overpass the oil and steel firms in the late stage. And also the

[^13]interaction between Chinese firms and Taiwan's firms shift to more bilateral that some Taiwan's firms turn to absorb the patents by their Chinese peers.

Table 4.1: Descriptive statistics about the co-patenting network

| Year | Nodes | Edges | Avg. Deg | Avg. W Deg | Year | Nodes | Edges | Avg. Deg | Avg. W Deg |

### 4.2.2 Hypothesis about the co-patenting network.

R\&D does not only generate new information but also enhances the firm's ability to assimilate and exploit existing information(Wesley.Cohen, et al 1989). The new information may refers to technology, technique, managerial structure, etc. The information can be kept in form of patent, trade secret, experience and established practices. The ability to generate,assimilate and learn is intangible too. In the research frame here, the patenting and citation networks is adopted as the proxy for these unmeasurable variables here.

The economic meaning of organization's position in the inter-organizational network have drawn many researchers' attention since 1990s(Powell et al 1996). However it is not conclusive that what the specific effects of the role played by different network structure is on firms' performance theoretically. Researchers used to adopt empirical ways to test the hypothesis about the networks.(e.g. Gautam Ahuja 2000,Akbar Zaheer 2005)

The centrality of the dominant is measured by using Freeman(1997)' s concept of "betweenness". The important idea here is that an a node is central if it lies between other actors on their geodesics implying that to have a large betweenness centrality, the node must be between many other nodes via their geodesics. So the higher the betweenness-centrality is, the more probable that the focal node get in touch with the existing knowledge resource that facilitate its innovation ability. Meanwhile due to the advantageous position in the network, the more central firm's economic performance may gain advantage as well.

Hypothesis 1: Betweenness centrality of the firm is positively related to its production efficiency level.
Hypothesis 2: Betweenness centrality of the firm is positively related to its wage level.
Hypothesis 3: Betweenness centrality of the firm is positively related to the innovation performance.
Closed innovation system and open innovation system are two main innovation systems. In the past, many companies believed that as long as they invested more heavily in $R \& D$ than their competitors and protected their intellectual property from spilling over, they could innovate faster and more radically than competitors and hence sustain their competitive advantage. This paradigm of innovation is called closed innovation which requires the aggressive control of internal knowledge from leaking outside (Herzog \&Leker, 2010). Nevertheless with more openness of existing information, open innovation system seems gain advantage over closed ones these days. Especially for those nodes bridging structure holes, they input more resources to build up the capability to assimilate knowledge from outsiders of the existing collaborators, which can bring in more outstanding innovation and economical performance. On the contrary nodes with higher constraint are more concentrated to strengthen the existing collaboration relations.

Hypothesis 4: Structural holes in the constraint are negatively related to a firm's production efficiency level. Hypothesis 5: Structural holes in the constraint are negatively related to a firm's wage level.
Hypothesis 6: Structural holes in the constraint are negatively related to a firm's innovation performance.
As to the innovation performance, new product intensity and the current year's count of invent patent application are adopted to quantify it.

Different from the statistics embedded in the co-patenting network, authority and hub scores can act as the proxy of innovativeness and absorptiveness bibliometrically. In the classical economic scenario, firms with more advanced technology usually can reap higher productivity gains. Meanwhile their peers endeavor to narrow the technological gap. Therefore it is meaningful to test which type of R\&D capability more crucial for the improvement of productivity.
Hypothesis 7: Authority scores are positively related to the production efficiency.
Hypothesis 8: Hub scores are positively related to the production efficiency.

### 4.3 Methodology

### 4.3.1 Estimate of efficiency

The main incentive for firms to improve the production efficiency or initiate the new product is to gain supernormal profit over their competing counterparts. To estimate the firm level efficiency the stochastic frontier model containing the firm level heterogeneity (G.Battese \& J.Coelli 1995) is adopted here to estimate the efficiency for firm $i$ in time $t$ here as bellow:

$$
\begin{align*}
Y_{i t}=x_{i t} \beta+E_{i t}= & x_{i t} \beta+V_{i t}-U_{i t} \\
& U_{i t}=z_{i t} \delta+W_{u}  \tag{4.3.1}\\
& t \in\{1,2, \ldots T\}
\end{align*}
$$

where $Y_{i t}$ is the logarithm of gross output, $x_{i t}$ are logarithms the input of production along with the $t$ th period.$\beta$ is the parameters needed to be estimated, $V_{i t}$ is assumed to be iid $N\left(0, \sigma_{v}^{2}\right)$ and $U_{i t}$ is non-negative random variables,associated with the technical inefficiency of production, $W_{u}$ is defined by the truncation of normal distribution with zero mean and a homogeneous variance $\sigma_{U}{ }^{2}$ so $U_{i t}$ is obtained by truncation (at zero) of the normal distribution $N\left(z_{i t} \delta, \sigma_{U}{ }^{2}\right)$ of firms over time. In order to contain heterogeneity of inefficiency distribution, $z_{i t}$ is taken as a vector of explanatory variables associated with the technical progress of firm i's production in t . And $\delta$ are the parameters to be estimated. Furthermore the Farrell efficiency $E\left(-U_{i t}\right)$ labelled as $B C 95$ (G.Battese \&J.Coelli 1995) can be derived based on the regression result with the inferred conditional density function of $f_{\left.U\right|_{i t}}$.

$$
\begin{array}{r}
f_{U \mid E=e}(u)=\frac{\exp \frac{-1}{2}\left[\frac{\left.\left(u-\mu^{2}\right]\right)}{\sigma_{\star}^{2}}\right]}{\sqrt{2 \pi} \sigma_{\star} \Phi\left(\frac{\mu_{\star}}{\sigma_{\star}}\right)} \\
\mu_{\star}=\frac{\sigma_{V}^{2} z \delta-\sigma_{U}{ }^{2} e}{\sigma_{V}{ }^{2}+\sigma_{U}{ }^{2}} \text { and } \sigma_{\star}{ }^{2}=\frac{\sigma_{U}^{2} \sigma_{V}^{2}}{\sigma_{U}{ }^{2}+\sigma_{V}{ }^{2}}  \tag{4.3.2}\\
E\left(-z_{i t} \delta-W_{i t}\right)=E\left(-U_{i t}\right)=\int_{0}^{+\infty}-u f_{U \mid E=e}(u) d u .
\end{array}
$$

And $\Phi$ is the cumulative distribution of standard normal distribution. And time-effect $\tau$ is included both in the main part and the residual part which can reflect the Hicksian neutral progress and the logarithm of Farrell efficiency's linear change with time(G.Battese \&J.Coelli 1995). Moreover according to Olsen, et al.(2011) the marginal effect of $z_{k i t} \in z_{i t}$ on the Farrell efficiency can be estimated as bellow:

$$
\begin{array}{r}
\frac{\partial E[\exp (-U)]}{\partial z_{k i t}}=\frac{\delta_{k}(1-\gamma) \exp \left(-\mu_{\star}+1 / 2 \sigma_{\star}^{2}\right)}{\Phi\left(\frac{\mu_{\star}}{\sigma_{\star}}\right)} \times \\
\left(\frac{\phi\left(-\sigma_{\star}+\mu_{\star} \backslash \sigma_{\star}\right)}{\sigma_{\star}}-\frac{\Phi\left(-\sigma_{\star}+\mu_{\star} \backslash \sigma_{\star}\right) \phi\left(\mu_{\star} \backslash \sigma_{\star}\right)}{\sigma_{\star} \Phi\left(\mu_{\star} \backslash \sigma_{\star}\right)}-\Phi\left(\frac{\mu_{\star}}{\sigma_{\star}}\right)\right) \tag{4.3.3}
\end{array}
$$

Therefore the derived firm-level $B C 95$ can be regressed on the patent network related variables, agglomeration related variables and other control variables, which can give us a glimpse into how R\& D network and agglomeration affect the efficiency.

Moreover the main part form of model adopts the translog production as bellow:

$$
\begin{align*}
\log \left(\text { OutPut }_{i t}\right)= & \beta_{0}+\beta_{1} \log \left(\text { FxAsset }_{i t}\right)+\beta_{2} \log \left(\text { Employee }_{i t}\right)+0.5 \beta_{3} \log ^{2}\left(\text { FxAsset }_{i t}\right) \\
+ & \left.0.5 \beta_{4} \log ^{2}\left(\text { Employee }_{i t}\right)+\beta_{5} \log \left(\text { Employee }_{i t}\right) \log \text { FxAsset }_{i t}\right)+\tau  \tag{4.3.4}\\
& \text { and } \quad U_{i t}=\log \left(\text { CumuPat }_{i t}\right)+\tau+W_{i t}
\end{align*}
$$

In addition translog can be taken as a Taylor series approximation of CES (i.e. constant elasticity of substitution ) function $Y=\left(\omega_{1} X_{1}^{\rho}+\omega_{2} X_{2}^{\rho}\right)^{1 / \rho}$ as bellow:

$$
\begin{align*}
& x=X_{1} / X_{2} \\
& \log g(x)=\log \left(Y / X_{2}\right)=\rho^{-1} \log \left[\omega_{1} e^{\rho \log (x)}+\omega_{2}\right] \\
& \frac{\partial \log g}{\partial \log x}=\omega_{1} x^{\rho} /\left(\omega_{2}+\omega_{1} x^{\rho}\right)=a \\
& \frac{\partial^{2} \log g}{\partial \log x^{2}}=\rho \omega_{2} \omega_{1} x^{\rho} /\left(\omega_{2}+\omega_{1} x^{\rho}\right)^{2}=2 \rho a b \\
& 2 b=\omega_{2} /\left(\omega_{2}+\omega_{1} x^{\rho}\right)  \tag{4.3.5}\\
& \quad \text { for } \quad x \xrightarrow{P} x_{0} \\
& \log (Y)=\log \left(X_{2}\right)+\log g(x) \\
& \approx \log \left(X_{2}\right)+\log \left(x_{0}\right)+a \log (x)-a \log \left(x_{0}\right)+b\left[\log (x)-\log \left(x_{0}\right)\right]^{2} \\
& \approx \alpha_{1} \log \left(X_{1}\right)+\alpha_{2} \log \left(X_{2}\right)+\alpha_{3} \log ^{2}\left(X_{1}\right)+\alpha_{4} \log ^{2}\left(X_{2}\right)+\alpha_{5} \log \left(X_{1}\right) \log \left(X_{2}\right)
\end{align*}
$$

The translog production takes the yearly net fixed assets and employee as the main input. Although intermediate product can be found in ASIE ,it is excluded because it causes the misspecified model that the estimated residuals is in right-skewed distribution (i.e. the $U_{i t}$ are all negative so all the firms are in full-efficient operation.) And logarithm of cumulative count of patent applications and $\tau$ th year are taken to be $z_{i t}$. All the calculation is carried out with the frontier package in R.

### 4.3.2 Poisson fixed effect model

To estimate the co-patenting network's effect on the count of patent application, Poisson fixed effect is adopted here(Baltagi, 2013). The model for firm i in year $t$ takes the form as bellow:

$$
\begin{align*}
\operatorname{Pr}\left(Y_{i t}=y_{i t} \mid x_{i t}\right) & =\frac{e^{-\lambda_{i t}} \lambda_{i t}^{y_{i t}}}{y_{i t}!}  \tag{4.3.6}\\
\log \lambda_{i t} & =\mu_{i}+x_{i t} \beta
\end{align*}
$$

where $\mu_{i}$ refers to the unobservable individual specific effects, just as the fixed effect panel model. Thereafter $E\left(y_{i t} \mid x_{i t}\right)=\operatorname{var}\left(y_{i t} \mid x_{i t}\right)=\lambda_{i t}$ and for continuous variable $x_{i t k}$ in $x_{i t}$ the marginal effect is $\frac{\partial E\left(y_{i t} \mid x_{i t}\right)}{\partial x_{i t k}}=\lambda_{i t} \beta_{k}$. Although many researcher criticize this model for its pre-requisite $E\left(y_{i t} \mid x_{i t}\right)=\operatorname{var}\left(y_{i t} \mid x_{i t}\right)$, it is adopted as other models cannot bring about converging maximum likelihood estimation result for the data.

Besides Burt's constraint and betweenness centrality, one year lag and current year's R \& D expenditure is included here, because ASIE only provides it in year 2005, 2006, 2007 and 2010. As R \& D expenditure in 2008 and 2009 is missing, data of year 2010 is dropped.

### 4.3.3 Variables

All the variables involved are as bellow:
Dependent variables:
$B C 95$ : Farrell efficiency derived from stochastic frontier model (G.Battese \&J.Coelli 1995)
WageBenefit $_{\text {per }}$ :annual average wage plus benefits per capita.
Newproductintensity: The new product output ratio to the total output which is only available in year 19982007 and 2010.
patentcount: The current year's count of newly filed in patent application.
Control variables:
Output: priced adjusted total output of firm i in year t .
Employee:Total count of Employee of firm in year t .
CumuPat:one year lag cumulative number of invent patents beheld by the firm in year t .
Ownership: factor variables includes private(baseline), state-owned, collective-owned, HMT-owned and foreign-owned. I use the percentage of these 5 types' percentage of entity recorded in ASIE. Besides this way registration types are also recorded in ASIE, but they are more comparatively static than the share of entity(Nie Huihua, 2012).Specially private-owned is taken as baseline altogether with 1 as state-owned, 2 as

HMT owned, 3 as foreign-owned and 4 as collective-owned.
Independent variables:
Burt'sconstraint: one year lagged constrain value calculated as the function 4.2.2.
betcent: one year lagged betweenness centrality calculated as the function 4.2.1
authority one year lagged authority as the function 4.2.4
hub one year lagged hub as the function 4.2.4
localization: $\log \left(E_{t}^{\text {sec,city }}-E_{i, t}^{\text {sec,city }}+1\right)$ where sec is the 2 digits sector of firm i and city is where the firm i is located. Localization can be seen as a proxy of Marshallian externalities.
urbdiver: urbanization diversity of manufacture sector apart from mining sector, which is based on the Herfindahl - Hirschman Index. And higher the urbdiver is the more diversified the manufacture sector of the focal city is in year t for the sector sec. urbdiver can be taken as the Jacobian diversification externalities.

$$
\begin{equation*}
\operatorname{urbdiver}_{t}^{\text {sec,city }}=\ln \left(\frac{1}{H_{i}^{\text {sec,city }}}\right), H_{i}^{\text {sec,city }}=\sum_{\text {set' } \neq \sec ^{\prime}}\left(\frac{E^{\text {sec }}{ }^{\prime} \text { city }}{E_{t}^{c i t y}-E_{t}^{\text {sec,city }}}\right) \tag{4.3.7}
\end{equation*}
$$

$s e c$ is the focal sector and $s e c^{\prime}$ is the all other sectors apart from focal sector.
urbanizationsize is the yearly total manufacturing sector's employees' count other than the focal firm in focal city, which is calculated as $\ln \left(E_{t}^{c i t y}-E_{t}{ }^{i}+1\right)$.
competition: yearly competition level of sector which firm i belonged to in the city where it is located. And the calculation is same as function 3.3.2.
$R \& D e x p$ : current year's $\mathrm{R} \& \mathrm{D}$ expenditure.
$R \& D e x p$ lag: last year's $\mathrm{R} \& \mathrm{D}$ expenditure.

### 4.4 Results

### 4.4.1 Overall results of the Farrell efficiency

The efficiency' results are derived from the regression of each sector. Due to the model's misspecification, the cumulative counts of patents is omitted for sector 32 and the year's variable is omitted for sector 33. In addition the main part of the model is misspecified for sector 43 which is recycling and disposal of waste. It can be reasonably inferred that the production process of sector 43 is at odds with other manufacturing sectors. In section 8.4 it summarizes the yearly distribution of efficiency of each sector, where we can find obvious trends of convergence in sector $13,14,15,16,18,19,20,21,23,26,27,30,31,34,35,36,37,39$ and 41 . On the contrary trends of divergence can only be found in sectors of petroleum, non ferrous metals processing and communication
equipment( 25,33 and 40 ). As to the most actively patenting sector 40 (communication equipment, computers and other electronics equipment), the distribution is bimodal. Especially the firms like Huawei, ZTE boast the outstanding efficiency apart from their domestic peers.

The shift trends can be partly explained by the patents filed as the section 8.5 shows. Especially the marginal contribution effects by patent monotonically decrease along the time in most sectors except those of tobacco, petroleum, chemical fiber and non ferrous metals(16, 25, 28 and 33). Although the patents application outburst after 2008, the contribution to the production's efficiency don't show the trend proportionately except the sector 25 (petroleum, coking and nuclear fuel process). As to the most actively patenting sector 40 (communication equipment, computers and other electronics equipment), the distribution is bimodal. Especially the firms like Huawei, ZTE boast the outstanding efficiency apart from their domestic peers.

### 4.4.2 Results of the regression

The observations included in the regression are those enlisted in networks based on their stock of patent. Therefore the data is a monotonically incremental unbalanced panel data. The regression can only probe into the mechanism of the existing firms in networks, but not estimate under what conditions a firm has the will to stretch out for a co-patenting partner or assimilate others' patent.

Pooling, fixed effect(FE) and random effect(RE) model are adopted as basic models. According to the Hausman test between FE and RE the regressors are not exogenous to the estimated errors. Moreover the FE model is not compliant with the homoscedasticity and serial uncorrelated hypothesis, which means that the estimator is lack of efficiency. Therefore robust estimators are adopted including intra-group heteroscedasticity and serial correlation robust estimator(Arellano 1987) and FEGLS/FDGLS(First difference general least squares). Nevertheless the existence of cross section dependence dampens the efficiency of these two alternatives to the basic models because cross section dependence implicates that covariance matrix of the residuals are not identical among the the groups(firms). Despite the heterogeneity of each firm, it is still reasonable to take the results of FE and FEGLS models as consistent.

As sections $8.6,8.8,8.9$ and 8.10 show, Burt's constraint is negatively related with the technical efficiency, wage benefit level, new product intensity and patent count with strong significance. On the other side betweenness centrality has only significantly positive affect on patent count, meanwhile its positive effect on Farrell efficiency is questionable. It can be inferred that betweenness in the total graph can not bring about direct effect on firms' business performance, but it can subtly affect it by boosting firm's patent application and stock of knowledge. On the other side Burt's constraint not only boost the patent application but also affect firms' business performance directly.

With respect to the effect of the agglomeration externalities, scale related variables(localization and urbanization size) outshines the inter-sector diversity externalities for the Farrell efficiency. Even urbanization diversity show to be negative for the production efficiency. As to the effect on wage benefit level and new product intensity, both effects don't show the solid significance. On the contrary competition has positive effect on the wage level unsurprisingly. The estimators about the externalities are not that convincing as sample selection can cause bias in estimation.

With respect to each firm's attributes, the production scale has positive effects on the wage benefit level Per capita, new product intensity and patent count. In the perspective of ownership, introduction of foreign, HMT or collective share holders can have positive effect on the production efficiency. And foreign and collective share holders have more propensity to provide higher wages than state-owned share holders. Moreover introduction of foreign share holders have significant propensity to launch new product. As last the stock of invents has significant effect on the wage benefit level and launching new product.

Same as regressing Farrell efficiency on co-patenting network, according to section 8.7 the citation network data are wrangled with serial correlation, scedasticity and cross-section dependence. By means of Hausmman tests, estimators by FE, Arrleo-vcovHC and FEGLS are consistent. Therefore authority have significant positive effect on Farrell efficiency, so firms being heavily citied are more advanced to sharpen their efficiency. On the other side, firms good at absorbing others' patents(Hub) have no significant divergence from others. As to the externalities, urbanization size have positive effect, but the inter-industries diversity have negative effect. Moreover,intra industry diversity or competition level have negative effect. So Marshallian externalities are preferred for improving the Farrell efficiency.

## Chapter 5

## Conclusions

In chapter 2 the ASIE database is linked with SIPO's and EPO's patent databases respectively with the adoption of data science techniques. Compared with the existing matched results, the linkage between ASIE and SIPO's patent database are multiplied in addition to the improvement of linking precision. Other than firm names, unique organization codes is fully used along the time span, which better cope with the modification of registry info. Furthermore the linguistic obstacles are tamped between ASIE and PATSTAT's citation database. The linked results obviously enrich the perspectives to probe into Chinese manufacture firms' micro performance

In chapter 3 localization quotients and employee weighted KD function are adopted respectively to estimate the degree of agglomeration along the ASIE's time span. The former index is a classical way based on the discrete space presumption. Other than taking a arbitrary value as the threshold, confidence intervals is derived city-sector wise for each year. For the values out of the confidence interval, they are divided into concentration and dispersion groups. On the other side with scraping the geographic information for the ZIP codes in ASIE, each firm is attached with a approximated latitude and longitude. Thereafter I derive KD envelop curves and estimate global localization indices. Based on the estimated results it is found that discrete localization have overestimating bias for agglomeration. Moreover several patterns of geographic distribution evolving progress are summarized.To estimate the relation between firms' size and agglomeration, SAC and SDEM models are adopted to complement the results of basic panel models because cross section dependence exists overwhelmingly. Based on the results of spatial direct and indirect effects, Marshallian externalities are preferred to Jacobian externalities for most sectors' large firms. And the stock of patents have diverging effect. Models' goodness of fit are not solved here as there is no decisive test about the non-nested spatial panel models.

In chapter 4 the co-patenting network is constructed from scratch based on the linking results. According
to the visualization and descriptive statistics, the co-patenting network have grown more extensively and sparsely since 1985. Through outcomes of betweenness centrality it is found that the universities in China dominantly occupy central positions in the information flow. On the other side focusing on DOCDB numbers the the citation network centering on Chinese firms are constructed from scratch. According the citation relationship among different regions, United States, Japan, Germany, Taiwan and South Korea maintain the most active interactions with China. Furthermore based on the hub and authority scores(HITS), firms from theses countries overwhelmingly ranks higher than Chinese counterparts in authority, even though Huawei Technology and ZTE uprise in later stage. On the contrary Chinese firms act as the main hubs to absorb technology. In addition, it probes into the effect of co-patenting network's effect on production efficiency, wage level and innovation performance as well as citation network's effect on production efficiency. Especially stochastic frontier models with time-variant efficiency are adopted, through which it is found most sectors experienced convergence of Farrell efficiency and declining marginal effect of incremental invent patents. As to the effect of co-patenting network, Burt's constraint have significantly negative effects on efficiency, wage level and innovation performance. On the contrary betweenness centrality only affects firms' performance indirectly by boosting patent application. In the citation network, firms with higher authority scores boost higher production efficiency. With respect to the effect of agglomeration, sample selection bias probably dampens the derived results. Compared with total number of firms in ASIE, only a small fraction is enlisted in the co-patenting and citation networks. Therefore more appropriate regression model is required to integrate the network and agglomeration.

At last it is ferociously worthy to continue deeper research into the networks and agglomeration's effect on firm's micro level performance. Firstly the citation networks deserve more scrupulous analysis as it is in close relation with firms' technological progress. Secondly firm sorting mechanism is not enrolled here. Firms' location is ordinarily accompanied with the equilibriums of different economic sectors such as land, labor and consumption markets. A more convincing method need to be embedded with broader picture of economy. Thirdly cross dependence exists overwhelming with nearly all regression models about firms. More relaxed econometrics models are needed to cope with this to improve estimators' efficiency. Fourthly micro level network analysis about firms has been emerging these years. Newly developed econometric tools deserves being sharpened for the application to these micro-level databases.

## Chapter 7

## Appendix to Chapter 3

7.1 Manufacture classification codes of GB/T 4754-2002

| code | Sector names Chinese |
| :--- | :--- |
| 13 | 农副产品加工业 |
| 14 | Sector names English |
| 15 | 食品制造业 |
| 饮料制造业 | Frocessing of food from agric．products |
| 16 | 烟草制品业 |
| 17 | 纺织业 |
| 18 | 纺织服装，服饰业 |
| 19 | 皮革，毛皮，羽毛及其制品和制鞋业 |
| 20 | Tobaccoge，alcohol and tea product |
| 21 | 木材加工和木，竹，藤，棕，草制品业 |
| 家具制造业 | timberther，fur，feather and related products bamboo，rattan，palm，and straw products |
| 22 | 造纸和纸制品业 |
| 23 | 印刷和记录媒介复制业 |
| 24 | 文教体育用品制造业 |
| 25 | 石油加工，胨焦及核燃料加工业 |
| 26 | 化学原料和化学制品制造业 |
| 27 | 医药制造业 |

Table 7．1：Manufacture classification codes of GB／T 4754－2002

### 7.2 Mapping LQ values for cities

Figure 7.1: Mapping LQ values for cities(sector 13-17)

Figure 7.2: Mapping LQ values for cities(sector 18-22)

Figure 7.3: Mapping LQ values for cities(sector 23-27)

Figure 7.4: Mapping LQ values for cities(sector 28-32)

Figure 7.5: Mapping LQ values for cities(sector 33-37)

Figure 7.6: Mapping LQ values for cities(sector 39-43) ${ }^{28}$

### 7.3 Moran' I test result for year 1998, 2006 and 2013

${ }^{28}$ sector 43 was newly enlisted from year 2002

Table 7.2: Moran' I test result for year 1998, 2006 and 2013

| sector | year | Moran'I statistic | p -value | sector | year | Moran'I statistic | p -value | sector | year | Moran'I statistic | p-value |
